GSA Bulletin MS# 21894, Data Repository item 2001135 Thouret et al., 'Geology of El Misti volcano near the city of Arequipa, Peru'

APPENDIX 1 A. ⁴⁰Ar / ³⁹Ar dates with analytical data

Two ignimbrites which form the basement of the Misti in the canyon of Río Chili (Fig. 2B) were dated by laser step heating on single biotite grains. Biotites from sample Mi 214 were extracted from a pumice 3 cm across in a pumice-rich unit; biotites of sample Mi 215 are idiomorphic phenocrysts from a pumice-poor unit 50 m beneath the latter. The samples were gently crushed and sieved; 800-micron-sized biotites were concentrated and grains for laser were hand-picked under a binocular microscope. Lavas from Misti mainly andesitic (Fig 6) were dated on whole rock because suitable minerals cannot be separated. About 100 mg of sample were used for high-frequency furnace step heating experiment.

The samples were irradiated in the 5C position of the McMaster University nuclear reactor (Hamilton, Canada). The samples Mi 214 and Mi215 were irradiated for 5 hours, together with the Fish Canyon Tuff sanidine (28.02 Ma; Renne et al, 1998) as neutron flux monitor. The Misti lava samples (whole rock) were irradiated for 1.5 hour with cadmium shielding together with the DRA sanidine (Wijbrans et al, 1995) as neutron flux monitor. An intercalibration of this standard with the Fish Canyon Tuff sanidine (28.02 Ma) gave us an age of 25.58 Ma that is used in this study.

⁴⁰Ar-³⁹Ar age determinations were performed by M. Fornari (IRD and UMR 6525 Géosciences Azur) at the Université de Nice, Sophia-Antipolis. Experimental techniques are described in detail by Ruffet et al. (1991) for the laser heating and by Féraud et al. (1982) for the high-frequency furnace heating procedures. The whole-rock sample analysis is performed with a mass spectrometer composed of a 120° M.A.S.S.E. tube, a Baur-Signer GS 98 source and a Balzers electron multiplier. For laser heating experiments, the gas extraction was carried out by a Coherent Innova 70-4 continuous laser. The mass spectrometer is a VG 3600 working with a Daly detector system. The typical blank values of the extraction and purification laser system are ranging from 9-5 x 10⁻¹³ ccSTP for ⁴⁰Ar, 8-1 x 10⁻¹⁴ ccSTP for ³⁹Ar, 2-1Êx 10⁻¹³ ccSTP for ³⁷Ar, and 7-3 x 10⁻¹⁴ ccSTP for ³⁶Ar, measured every third step. The criteria for defining a plateau age were the following: (1) the plateau should contain at least 70Ê% of released ³⁹Ar, (2) there should be at least three successive steps in the plateau, and (3) the integrated age of the plateau should agree with each apparent age of the plateau within a 2 sigma (2σ) interval. All errors are quoted at the 1σ level of confidence and do not include the errors on the age of the monitor. The error on the ⁴⁰Ar*/³⁹Ar_K ratio of the monitor is included in the plateau age error bar calculation (see Table1).

The Mi 214 biotite age spectrum displays a plateau age of 13.12 ± 0.05 (Fig. 1) corresponding to 77% of the ³⁹Ar released, and following a more disturbed section probably due to chloritization. The Mi 215 biotite does not give a plateau age following our criteria, but a weighted mean age of 13.8 ± 0.1 Ma calculated on 5 concordant temperature steps (corresponding to 65% of the total ³⁹Ar released) may represent the best estimate of the age of this rock. This is straigthforward due to the fact that this age is slightly higher than the plateau age displayed by the sample Mi 214 located above this formation. It is also possible that this biotite was affected by chloritization. These ages are much older than the fission track age of 2.42 ± 0.11 Ma obtained on the uppermost ignimbrite unit termed 'white sillar' (Vatin-Perignon et al., 1996).

The sample Mi 100, corresponding to a fine grained, microcrystaline lava flow with millimetric phenocrysts of amphibole, displays an age spectrum characterized by decreasing

apparent ages versus temperature, characteristic of 39Ar recoil during irradiation. However, a plateau age of 833 ± 6 ka (Fig. xB1) accounting for 74% of the total ³⁹Ar released for the temperature steps 850° to 1040° C could be obtained from the most potassic phases (probably grounmass) of the rock, as shown by the 37ArCa/39ArK spectrum (Fig. 1) -³⁶Ar/40Ar versus ³⁹Ar/40Ar correlation plot (not given) on all data displays a similar age of 833 ± 7 ka with an initial ⁴⁰Ar/36Ar ratio of 297.3 ± 1.2 of atmospheric composition, but corresponding to a low quality fitting (MSWD = 8.3).

The sample Mi 50 displays a disturbed age spectrum probably due to 39Ar recoil, but displays a plateau age of 112 ± 6 ka that represents 84.5% of the total ³⁹Ar released (steps 700-1350°C) (Fig. 1) could be obtained on the K-rich phases (last steps excepted). The ³⁶Ar/⁴⁰Ar versus ³⁹Ar/⁴⁰Ar correlation plot (not given) on the plateau fraction does not fit very well, but gives a similar age of 109 ± 4 ka with an atmospheric initial ⁴⁰Ar/³⁶Ar ratio of 296.2 ± 1.7 (MSWD = 5.2).

APPENDIX 1 B. Thermoluminescence dating method (M. Frechen)

All measurements were carried out on the 4-11 μ m grain-size fraction using the preparation technique described in Frechen et al. (1996) for all samples. All samples were irradiated in eight different dose steps (five discs per dose step) using a Cobalt-60 source. Alpha irradiation was undertaken by a 241Am source to determine the alpha effectiveness (avalue). As the 1-sigma standard deviation of the measured palaeodose equivalents of the avalues were large due to large scattering of the glow curves, an average value of 0.01 ± 0.002 was used for all samples. After irradiation all fine grain samples were preheated at 150° C for 16 hours in order to eliminate the unstable part of the glow curves. All discs were left at room temperature for at least 4 weeks after irradiation. Measurements were carried out using an automated Risö TL/OSL Reader. A filter combination of Schott BG-39 and Chance Pilkington HA-3 was placed between photomultiplier and aliquots. After the 25 seconds of IR shine down, carried out by an array of 32 diodes emitting a wavelength of 880 \pm 80 nm, the same discs were measured immediately by TL. The aliquots were measured with a heating

rate of 5°C/sec up to 450° C. Equivalent doses were obtained for the tephra samples by additive dose methods by integrating the 300-400°C range and the age plateau which is defined in an equivalent dose plot larger than 50°C yielding constant ED values (Berger 1991).

Luminescence Methods

Further information about principles of TL are found in Aitken (1985) and Wintle (1997). Thermoluminescence (TL) and Optical Stimulated Luminescence (OSL) is the light emitted from crystals like quartz, feldspar or zirconium when they are heated or stimulated with light after receiving a natural or artificial radiation dose. In nature the radiation results from the decay of radioactive isotopes like 235U, 238U, 235Th, 40K and some minor isotopes and cosmic rays. The luminescence clock (signal) is set to zero for volcanic material in respect to heating up of the minerals or growth and cooling of minerals and volcanic glass after eruption. With respect to volcanic glass the last cooling date of the minerals or glass or the eruption age will be determined.

The dating of volcanic material was attempted in the early 1970s when Wintle (1973) described anomalous fading by measuring feldspars from rhyolites near Naples and basalts from Iceland and France. Since that time it has been difficult to overcome the problem of anomalous fading which is understood as a rapid initial fading of the signal from feldspar after irradiation. This complicating property does not seem to conform a simple time dependent behaviour. A rapid initial fading is followed by a much slower TL loss with time. In the case of the Misti pumice samples, a delay of at least 4 weeks was applied between irradiation and TL measurements in order to minimise the effect of fading.

The whole rock sample analysis is performed with a mass spectrometer composed of a 120° M.A.S.S.E. tube, a Baur-Signer GS 98 source and a Balzers electron multiplier. For laser heating experiments, the gas extraction was carried out by a Coherent Innova 70-4 continuous laser. The mass spectrometer is a VG 3600 working with a Daly detector system. The typical blank values of the extraction and purification laser system are ranging from 9-5 x 10-13 ccSTP for 40Ar, 8-1 x 10-14 ccSTP for 39Ar, 2-1 x 10-13 ccSTP for 37Ar, and 7-3 x 10-14 ccSTP for 36Ar, measured every third step.
