Soreghan, Soreghan, Poulsen, Young, Eble, Sweet, \& Davogustto<br>"Anomalous Cold in the Pangaean Tropics"

## GPS Locations

For outcrop (1) and borehole (2) locations cited in the manuscript (Figure 1):
(1) $38^{\circ} 46.354 \mathrm{~N}, 108^{\circ} 53.024 \mathrm{~W}$ and $38^{\circ} 36.291 \mathrm{~N}, 108^{\circ} 53.061 \mathrm{~W}$
(2) $38^{\circ} 46.052 \mathrm{~N}, 108^{\circ} 48.861 \mathrm{~W}$

## Gravity Analyses

The gravity survey used a LaCoste-Romberg Type D gravimeter. The station interval was 32 m (Figure DR1), and the station locations were determined by differential GPS measurements. Three gravity observations were averaged at each station, and a linear-drift correction applied. The reduced free-air gravity anomaly included a free-air correction, a latitude correction and a tidal correction as detailed below. The program GM-SYS was used in $21 / 2 \mathrm{D}$ gravity modeling mode and accounted for canyon topography over a 3 km cross-section centered on the Massey \#1 well. The standard value for basement density, $2.67 \mathrm{gm} / \mathrm{cc}$, was chosen, and an optimal density for the fill, $1.93 \mathrm{gm} / \mathrm{cc}$, was determined by modeling. Velocities from a nearby shallow refraction/reflection seismic survey (see Fig. DR1 and Suarez, 2007) were consistent with the densities used in gravity modeling.

Drift Correction-For the linear drift correction, we established a base station, recorded readings here at the beginning and end of the survey and used the difference:

$$
d c_{s}=\frac{g_{o b s b 2}-g_{o b s b 1}}{t_{b 2}-t_{b 1}}\left(t_{s}-t_{b 1}\right)
$$

Where $\mathrm{dc}_{\mathrm{s}}$ is the drift correction for the station, tb1 and $\mathrm{t}_{\mathrm{b} 2}$ are the times at the start and the end of the survey in the base station, gobs are the null readings at the base and $t_{s}$ is the time at the station.

Latitude Correction--The latitude correction is obtained by differentiating the international gravity formula with respect to latitude:
$L c=\left(1 / R_{e}\right) \Delta g_{t} / \Delta \phi$
$L c=0.811 \sin (2 \phi) \Delta S \mathrm{mGal} / \mathrm{Km}$

Where $\varphi$ is the latitude, $\Delta \mathrm{S}$ is the horizontal distance from the base station. The correction is always added to $g$ as one moves toward the equator.

Free Air Correction-We accounted for elevational changes between stations by reducing all to a common datum. The Free air correction is then obtained by deriving the scalar equation of the gravity acceleration with respect the radial distance:
$c_{f a}=2 g / R_{e}$
$c_{f a}=0.3086 h \mathrm{mGal} / \mathrm{m}$

The free air correction is added to or subtracted from the field reading depending on whether the station is above or below the datum, respectively.

Bouguer Correction--The Bouguer correction accounts for the mass between the datum surface and the stations and is given by:
$c_{b}=2 \pi G \rho h$
$c_{b}=0.04192 \rho h \mathrm{mGal} / \mathrm{m}$
Terrain Correction--The terrain correction accounts for topographic undulations in regions surrounding each station. Using a detailed topographic map we divided the nearby region using concentric circles and radial lines to construct sectors whose areas increase with distance from the station; then the gravity effect of each sector is calculated from the formula:

$$
T_{g}=G \rho \theta\left(r_{0}-r_{i}\right)+\left(r^{2}{ }_{i}+\Delta z^{2}\right)^{/ 2}-\left(r^{2}{ }_{0}+\Delta z^{2}\right)^{/ 2}
$$

Figure DR1: Location map for gravity profiles in western Unaweep Canyon (see Figure 1 of manuscript for additional location information). Note that two profiles were conducted (A and B). Profile A is highlighted as these link to well results, but results for Profile B match those for Profile A in exhibiting a U-shaped basement as a best fit. Topographic bases are portions of the Fish Creek (Colorado) $71 / 2$-minute quad (U.S. Geological Survey, 1972) and the Two V Basin (Colorado) $71 / 2$-minute quad (U.S. Geological Survey, 1969).

## Palynology

Palynological results from outcrop and core samples are also reported in Soreghan et al. (2007). Figure DR2 illustrates representative Paleozoic palynomorphs recovered from the basal diamictite encountered in core from the Massey well (point 2 on Fig. 1). All samples were processed and analyzed by C.F. Eble at the Kentucky Geological Survey. Multiple sample splits were processed, each time using virgin sample containers, to exclude the possibility of contamination. The recovered palynomorph assemblage is indicative of Late Pennsylvanian-Early Permian age, and most probably Early Permian.

Figure DR2: Photomicrographs of palynomorphs: (A) Vesicaspora wilsonii (long axis 67
$\mu \mathrm{m}$; (B) Florinites (long axis $45 \mu \mathrm{~m}$ ); (C) Endosporites globiformis (long axis $90 \mu \mathrm{~m}$ ); (D Thymospora thiessenii (long axis $23 \mu \mathrm{~m}$ ); (E) Laevigatosporites minor (long axis $43 \mu \mathrm{~m}$ ); (F) Lycospora granulata (long axis $39 \mu \mathrm{~m}$ ).

Lycospora granulata

## Scanning Electron Microscopy (SEM)

Four samples of poorly consolidated upper Paleozoic diamictite were processed to clean and isolate quartz for SEM analysis of surface textures. Two of the samples are from the diamictite exposed in western Unaweep Canyon (point 1 on Fig. 1), and two are from the diamictite recovered in the core ( 315.3 and 318.2 m depths) from the Massey well (point 2 on Fig. 1). Samples were disaggregated by immersion in a dilute dispersant of sodium carbonate and subsequently treated with the citrate-bicarbonate-diothionite (CBD) method to remove iron oxides (Mehra and Jackson, 1960; Janitzky, 1986). After sieving to isolate the coarse-grained ( $500-2000 \mu \mathrm{~m}$ ) sand fraction, 16-22 quartz grains per sample were randomly selected and mounted for detailed examination on a scanning electron microscope (SEM, Zeiss DSM-960A). Microtextures were identified and logged following established standards and techniques (Mahaney, 2002). All features logged exhibit slight to moderate precipitation coatings, indicating their antiquity (Fig. 2F). Occurrence frequency of features is tabulated in Table DR2 (categories from Mahaney, 2002) where data from Mahaney and Kalm (2000) are also tabulated for comparison. Several authors have established that some microtextures uniquely identify specific transport processes (references below). For example, gouges, grooves and troughs reflect grain-to-grain contact under high-stress conditions, most characteristic of glacial till of varying geologic age (Mahaney et al., 1996; Mahaney and Kalm, 2000; Mahaney, 2002; Van Hoesen et al., 2004). In contrast, v-shaped cracks, edge rounding and breakage blocks reflect fracturing formed by percussion (i.e., saltation) dominant in fluvial systems (Mahaney and Kalm, 2000). Finally, polygenetic textures are those produced under a variety of conditions, such
as conchoidal fractures that could reflect either grain crushing in a glacial environment or grain fracturing in a fluvial environment (Mahaney, 2002). Hence, the textural classification into 'high-stress,' 'percussion,' and 'polygenetic' categories enables a graphical simplification of textures meant to highlight processes most indicative of glacial versus fluvial environments.

## Compilation of Gravel-Bed River (GBR) Gradients

Data compilations on GBRs from various regions show maximum slopes of 0.006 (range
0.0005-0.006, average $=0.003, \mathrm{n}=16$ ) (Blair and McPherson, 1994) to .019 (range 0.0001-
0.0190; average $=0.0062, \mathrm{n}=37$ ) (Church and Rood, 1983). Reported slopes for various reaches of nonbraided GBRs in the modern Rocky Mountains range between 0.000880.026 (average $=0.0084, n=24$ ), with only two measurements exceeding 0.02 (Andrews,
1984). If the proximal Cutler Formation represents a proglacial system, as proposed by Soreghan et al. (2005), the slopes remain similar. Today, proglacial systems that reach to sea level exist only in mid- to high-latitude regions; these systems can be very steep (.02.07) within a few km of the ice margin, but follow highly concave profiles such that typical distal gradients are in the $10^{-3}$ to $10^{-4}$ range, with average gradients $<0.01$ over the entire glacial-terminus to coastal-plain distance (Fahnestock, 1963; Boothroyd and Ashley, 1975). As reconstructed from DEM data, for example, the average gradient on the midlatitude Nisqually River (Washington) from its inception at Nisqually Glacier to its coastal terminus 140 km distant is 0.0089 . Figure DR3 shows the paleogeographic reconstructions for the Cutler system.

Figure DR3: Paleogeography of Uncompahgre-Paradox region during Cutler-Unaweep time, with distribution of lowstand (glacial) depositional systems and location of highstand (interglacial) shoreline positions (green dashed line; Condon, 1997). Multiple marine limestones within the lower Cutler Formation as represented from outcrop and well data (Condon, 1997) were used to constrain the maximal highstand position. A-A' shows reconstructions of elevations at the ice terminus using a range of average depositional gradients (see text). Glacioeustatic amplitude shown at A is 100 m (Soreghan and Giles, 1999).

## Loess Geochemistry

Pedogenically modified loessites are those displaying pedogenic features (e.g. ped structure, melanization, root traces, etc) such as outlined in Kessler et al. (1999), Soreghan et al., (2002) and Tramp et al. (2004). Samples coded as loessite are from the middle portions of loessite units and those coded as 'weathered loessite' occur immediately adjacent (within 20 cm ) of a paleosol. The good correlation ( $\mathrm{r}^{2}=0.74$ ) of $\mathrm{TiO}_{2}$ and $\mathrm{Al}_{2} \mathrm{O}_{3}$ within the paleosols and weathered loessite (Fig. 3B) indicates that these immobile elements become concentrated as weathering proceeds (Nesbitt and Young, 1998). However, the lack of such a correlation within the loessite indicates that the variability is created by source rock variation in $\mathrm{TiO}_{2}$ and $\mathrm{Al}_{2} \mathrm{O}_{3}$. Note that the variation in $\mathrm{Al}_{2} \mathrm{O}_{3}$ in loessite is much smaller compared to paleosols. Given the well-sorted nature of the loessite on average, the variability in $\mathrm{TiO}_{2}$ is less than that exhibited in glacial diamictite (Nesbitt and Young, 1998), but the trend is identical nonetheless.

Table DR 3: Geochemistry of Upper Paleozoic Loessites and Paleosols (in wt\%)

| Sample ID | Lithology ${ }^{1}$ | Location ${ }^{2}$ | SiO2 | TiO2 | Al203 | Fe2O3 | MqO | CaO | Na2O | K20 | P205 | LOI |

Note: (1) LIthology: L=Loessite; L(L)=Sample immediately above paleosol; P=Paleosol; and P(W)=Weakly Pedogenic.
(2) Locality represents sample site: $\mathrm{BD}=$ Bravo Dome region, NM (see Kessler et al., 2001 for stratigraphic details) and CO= near Basalt, CO (see Tramp, et al., 2004 for stratiqraphic details). Data summarized from Soreqhan and Soreqhan, 2007.

## Climate Modelling

Late Paleozoic experiments were completed using GENESIS AGCM version 2.3 coupled to a 3-D dynamic ice-sheet model. GENESIS consists of an AGCM coupled to multi-layer models of vegetation, soil or land ice, and snow, with spectral resolution of T31 ( $\sim 3.75^{\circ}$ ) and 18 vertical layers (Thompson and Pollard, 1997). GENESIS is asynchronously coupled to a 3-D thermo-mechanical ice-sheet model (DeConto and Pollard, 2003) that is based on the vertically integrated continuity equation for ice mass. The ice geometry is determined by the surface mass balance, basal melting, and ice flow. Sea-surface temperatures and sea ice are computed using a 50-m slab ocean with diffusive heat. A series of Late Paleozoic experiments were completed with a range of atmospheric $\mathrm{CO}_{2}$ and orbital settings (Horton et al., 2007). Here we report on a simulation that produces the maximum continental ice extent. The simulation uses a palaeogeography and palaeotopography from the Paleogeographic Atlas Project's reconstruction for the Sakmarian (see http://pgap.uchicago.edu), atmospheric $\mathrm{CO}_{2}$ level of 140 ppmv , preindustrial levels of $\mathrm{CH}_{4}$ and $\mathrm{N}_{2} \mathrm{O}$, a $3 \%$ reduction in solar luminosity, and orbital settings that minimize Southern Hemisphere summer insolation (obliquity $=22^{\circ}$, eccentricity $=$ 0.06, precession $=270^{\circ}$. Montañez et al. (2007) report atmospheric $\mathrm{pCO}_{2}$ as low as 280 ppmv in the Late Paleozoic. We have used a value that represents one-half of this concentration, and is similar to Last Glacial Maximum values, in order to maximize glaciation. Specifying higher levels of atmospheric $\mathrm{pCO}_{2}$ raise the minimum elevation that will sustain glaciation. In western equatorial Pangaea, palaeotopography is 500-1500 m owing to the Central Pangaean Mountains.
