GSA Data Repository 2009272: The effects of flank collapses on volcano plumbing systems

Andrea Manconi, Marc-Antoine Longpré, Thomas R. Walter,

Valentin R. Troll and Thor H. Hansteen

The following supplementary material includes:

1. Details of magma density calculations procedures.

2. Details on construction of the finite element models and the assumed loading/unloading conditions.

3. Details on the effects of different melt percentages on elastic properties of the magmatic reservoir and on the effects of different magma reservoir shapes.

4. Details on limitations and the validity of the finite element models.

5. Discussion of the possible effects of mass-wasting on melt production beneath ocean island volcanoes.

6. Supplementary References.

7. Supplementary Tables and Figures:

> Table DR1: Sampling/outcrop localities, respective rock type and, where available, calculated density. Table DR2: Geometrical parameters used for the finite element simulations of the conical edifice and that of volcano flank collapse. Figure DR1: Effect of different melt% on the elastic properties of the storage zone. Figure DR2: Effect of shape of magma storage zone on decompression.

1. Magma density calculations procedures

Volcanic products of El Hierro were collected during two field campaigns and were subsequently analyzed for whole-rock and groundmass major element compositions. We estimated pre-eruptive magma densities for representative El Hierro samples (see Table DR1), following the procedure outlined by Spera (2000) and using initial volatile contents approximated on the basis of Dixon et al. (1997). That is, dissolved water contents were taken as $H_2O=3(P_2O_5)$ wt% and initial carbon dioxide as $CO_2=2(H_2O)$ by mass. El Hierro samples give a range of H_2O=1.4-4.0 wt% and CO_2=2.8-7.9 wt%, comparable to bulk volatile contents inferred by Dixon et al. (1997), for undegassed alkaline Hawaiian magmas. For the density calculations, we assumed f_{O2}=QFM+1, P=900 MPa (typical pressure of the main magma storage zone under Canarian shield volcanoes, see e.g. Klügel et al. 2005, Longpré et al. 2008 and Stroncik et al. 2008), and melts at their liquidus temperature, calculated using PETROLOG (Danyushevsky, 2001). The presence of phenocrysts in magma was also taken into account. For samples with <10 vol. % olivine + clinopyroxene, the density of the melt was taken as a reasonable approximation of the magma density. For samples with >10 vol. % olivine + clinopyroxene, the magma density was calculated using a melt density of 2,780 kg/m^3 (average from groundmass samples) and observed modal phenocryst proportions ($\rho_{olivine}$=3,400 kg/m^3 (~Fo$_{80}$) and $\rho_{clinopyroxene}$=3,200 kg/m^3). Plagioclase (due to its density nearly equal to melt density) as well as Fe-Ti oxide and amphibole (due to their small abundances) were considered negligible for these calculations.

2. Construction of the finite element models, loading/unloading conditions and mechanical properties

The finite element models described and discussed in our study were constructed using the commercial software ABAQUS™. The software and the related "Analysis User's

50   Manual" are available at www.simulia.com. For simplicity, the models are axisymmetric

51   (as shown in Fig. 2a), thus the edifice load was applied as a triangular load using the

52   formulation:

53    $$L(r) = \rho_v \cdot g \cdot Hi \cdot \left(1 - \frac{r}{R}\right) \qquad \text{(DR1)}$$

54   where L(r) is the load calculated at the radial coordinate (r), ρ_v is the density of the

55   volcanic material (2,700 kg/m^3), g is the gravitational acceleration (9.81 m/s^2), Hi is the

56   initial height of the edifice (6 km) and R is the radius at the base of the edifice (30 km,

57   cf. Gee et al., 2001). In a second step, we removed 3% of the initial load equivalent to

58   180 km^3 (see also Table DR2). Both the loading and the unloading step were simulated

59   using the FORTRAN user subroutine *DLOAD in ABAQUS. Far field boundary

60   conditions were applied by means of a set of infinite elements on the right side and at

61   the bottom of the models. The maximum dimension of the elements in the areas of

62   interest for pressure calculations was set to 100 m, as the best compromise between

63   resolution and computational time (Fagan, 1992).

64   Geometrical parameters Hi and R used to calculate the initial loads for all localities

65   were either collected from literature information or approximated based on analysis of

66   digital elevation models or bathymetric maps (see Table DR2). This procedure, as well

67   as the axial symmetric assumption of the edifices' loads, may have introduced

68   uncertainties in the initial edifice volume estimates. On the other hand, flank collapse

69   volumes considered in this study are well constrained. In our simulations, effects due to

70   collapse are distributed over the entire edifice, while in reality they are likely to

71   concentrate on particular portions of the volcanic system. For example, the effects of the

72   El Golfo debris avalanche were probably much more focused on the El Golfo volcano

73   (~2,000 km^3) than on the whole El Hierro edifice (~5,500 km^3), which would have led

74   to a higher effective unloading fraction on the former. For this reason, the assumption of

75   the unloading volume as portion of the total edifice compensates for the potential error

76   on the estimation of the initial volume.

77   The effects of seawater load and material redistribution due to collapse were tested in

78   separate models not explicitly shown in the main text for the following reasons: (1)

79   Assuming that the seawater load is invariant during the relative time span considered by

80   our models, its simulation does not affect the pressure changes caused by a static flank

81   collapse. (2) In the case of the El Golfo landslide, which is classified as a debris

82   avalanche, the materials are thought to have been redistributed as a relatively thin layer

83   over the seafloor covering an extended area and distances up to 60 km from the edifice

84   (cf. Gee et al., 2001). The latter inclusion in our simulations only slightly decreased the

85   retrieved pressure changes caused by the flank collapse in the area of our main interest,

86   i.e. the magma reservoirs located directly beneath the El Hierro edifice. Thus, the model

87   simplifications shown in the main text of the paper are valid for studying pressure

88   changes at magma chamber levels.

89   **3. Effects of melt % and of different shape of magma reservoir**

90   Numerical models of magma reservoirs commonly consider magma as an

91   incompressible fluid, with bulk modulus varying between 1 and 10 GPa (e.g., Huppert

92   and Woods, 2002; Pinel and Jaupart, 2005). Such assumptions imply that the

93   mechanical behavior of magma reservoirs is dominated by the properties of the melt

94   phase. However, petrological evidence suggests that magma plumbing systems, such as

95   those of e.g. El Hierro (Stroncik et al., 2008) and other Canary Island volcanoes (Klügel

96   et al., 2005; Longpré et al., 2008), as well as Kilauea volcano, Hawaii (Tilling and

97   Dvorack, 1993), may consist of a plexus of dike- and sill-like fractures in the uppermost

98   mantle, where partially crystallized magmas are stored. In our models, we thus consider

99   El Hierro's magma storage zone as a multiphase system, where molten and crystallized

100   material co-exist. From this assumption entails that the storage zone in our models is

101   more compressible than the surrounding rock, in agreement with several independent

102   analyses done on basaltic magmas (e.g., Ryan, 1980 and references therein; Blake,

103   1981).

104   Walsh (1969) derived theoretical relationships for the mechanical properties of a

105   crystal-melt mixture. This study assumes an elastic and isotropic matrix (hereinafter

106   identified by the subscript "c"), specified by its bulk modulus (K_c) and shear modulus

107   (G_c), and an elastic, isotropic and dilute suspension of ellipsoidal melt parcels

108   (hereinafter identified by the subscript "m"), which are characterized by their bulk

109   modulus (K_m), shear modulus (G_m) and geometric aspect ratio (minor/major axis

110   herein set to 0.001, cf. Ryan, 1980). The melt parcels decrease the effective elastic

111   response of the basaltic magmas.

112   Since basalts are organized in a millimeter scale, we consider that the assumption of an

113   isotropic elastic behavior for the magmatic reservoir (kilometer scale) as a whole, which

114   is defined by a unique value of "effective" elastic parameters, is reasonable. To

115   calculate the values of effective Young's modulus (E) and effective Poisson's ratio (ν)

116   for the magmatic reservoir used in our modeling, we exploited the following approach.

117   We first fixed the value of E_c=80 GPa and ν=0.25 for fully crystallized basalt (Ryan,

118   1980) and calculated K_c and G_c. In addition, we defined G_m as equal to 0 (fluids do not

119   support shear stresses), and we considered a range for K_m between 1 and 10 GPa

120   (Huppert and Woods, 2002; Pinel and Jaupart, 2005). Finally, we calculated the values

121   for the effective E and ν for crystal-melt mixtures (melt % from 0 to 100), using the

122   relationships proposed by Walsh (1969). In Figure DR1-A&B we show the results of

123   these calculations. Depending on the value of K_m, hence on the compressibility of the

124   melt phase, the mechanical setups defined by models 1-3 may represent the elastic

125   response caused by different ranges of melt percentages within the magma reservoir. In

126   Figure DR1-C&D we compare the decompression caused by the El Golfo landslide in a

127   profile beneath the edifice, corresponding to the axis of symmetry of the finite element

128   models, see Fig. 2A of the main text. Clearly, a relative increase of the melt percentage

129   in the storage zone (Figure DR1-D) causes a decrease of its overall elastic stiffness and

130   influences the elastic response of the magmatic reservoir, enhancing the effect of the

131   decompression due to mass unloading.

132   Furthermore, in Figure DR2 we compare the decompression occurring in a

133   homogeneous half-space with models that consider a range of shapes for the simulated

134   magma storage zone. Oblate-shaped (OS) reservoirs tend to favor slightly higher

135   pressure changes compared with spherical-shaped (SS) or prolate-shaped (PS)

136   reservoirs. However, the general directions of the vectors (i.e. from the bottom to the top

137   of the reservoir) as well as the magnitudes of the differential pressure are largely

138   unaffected.

139   The assumption of further heterogeneities, as for example a layered lithosphere, might

140   affect the pressure changes at shallow levels but, in our tests, had no major effect on the

141   magma reservoir surroundings. Based on these considerations, we can state that our

142   results give a conservative but realistic representation of static pressure changes caused

143   by surface mass-wasting at the discussed volcanoes.

144   **4. Limitations and validity of the models**

145   High pressures and temperatures, co-existence of several polyphase aggregates, volatiles

146   and fluids add complexity to the analysis of magma reservoir feedback processes using

147   simplified mechanical models. Nevertheless, for short time-scales, we consider the

148   assumption of an elastic regime appropriate, as that of the magma reservoirs as zones of

149   structural weakening causing localization of stresses (Kanamori, 1972; Gudmundsson,

150   1988). On longer time-scales, viscous effects may also play an important role in

151   determining the amount of stress changes in the magma reservoir surroundings

152   (Newman et al., 2006). Moreover, future studies may refine quantitative evaluations of

153   pressure changes due to volcano flank collapse by adding complexity to the geometries

154   of the volcanic edifices, collapse scars and magma plumbing systems. More complex

155   dynamic modeling and material properties, on the other hand, would allow better

156   assessment of feedback processes caused by the pressure gradients revealed by our

157   simulations. However, we argue that none of these potential improvements would

158   change the principal outcome of our work.

159   **5. Possible effects on melt production at ocean island volcanoes**

160   Differing unloading timescales and geometries for deglaciation (thousands of years,

161   sheet-like) and catastrophic debris avalanches on volcano flanks (minutes to days?,

162   wedge-like) imply different rates and structural patterns in the systems' accommodation

163   to the new stress conditions. In both cases, however, the net stress change, that is

164   decompression, is analogous and useful comparisons can be made with studies that have

165   investigated the effects of deglaciation on Icelandic volcanism. For example, Jull and

166   McKenzie (1996) have shown that ice unloading during deglaciation can cause increased

167   melt production in Iceland's spreading ridge system (see also Maclennan et al., 2002).

168   Using numerical models, these authors found that, despite largest decompression

169   amplitudes just below the ice sheet ($\Delta P = 20$ MPa), the maximum effect on mantle

170   melting was actually much deeper, at a depth of about 80 km. In the presence of both a

171   mantle plume and a spreading ridge, the young Icelandic crust and lithosphere are

172   warmer and more ductile than old oceanic or continental upper mantle. The resulting

173   melting interval is thus thick (about 100 km), from the base of the crust at 20 km depth

174   to the solidus at about 115 km depth.

175   The Icelandic case therefore differs considerably from pure hot-spot settings without

176   spreading ridge, such as Hawaii or the Canary Islands. There, the older and colder

177   oceanic lithosphere results in a significant mechanical boundary layer. Under these

178   conditions, the melting zone is thinner and restrained at much greater depth, i.e. in the

179   spinel and garnet (mostly) stability fields between about ~70-140 km depth (Watson and

180   McKenzie, 1991; Hoernle and Schmincke, 1993).

181   The above-mentioned considerations, combined with the results of our numerical

182   models, which imply negligible decompression at depths of magma generation, suggest

183   that the unloading due to large-scale volcano flank collapse is unlikely to cause effects

184   of similar magnitude on ocean islands as has been described for deglaciation periods in

185   Iceland.

Lava types are divided into four categories, according to modal mineralogy: 1) aphyric to sub-aphyric (<5 vol. % phenocrysts of olivine/clinopyroxene/plagioclase, called aphyric basalt); 2) plagioclase-phyric (5-40 vol. %, called plagioclase basalt, which is sometimes referred to as "trachytes" in the literature); 3) moderately olivine- and/or clinopyroxene-phyric (5-20 vol. %, called basalt) and 4) highly olivine-clinopyroxene-phyric (>20 vol. %, called ankaramites). In Figure 1, the first three types are encompassed under the "crystal-poor" category. Where available, stratigraphic position and calculated magma density is also given.

Table DR2: Geometrical parameters used for the finite element simulations of conical edifices that experienced a volcano flank collapse.

	Height [km]	Radius [km]	Edifice Volume [km³]	Collapse Volume [km³]	% initial load
Augustine	~1.2 [a]	3.2 [(*)]	13 [a]	0.3 [a]	0.4%
St. Helens	1 [(*)]	6 [(*)]	38 [b]	2.5 [c]	6.5%
Parinacota	1.5 [(*)]	5.5 [(*)]	45 [d]	6 [d]	13%
Teno	5.3 [e]	25 [e]	3,500 [(*)]	~50 [f]	1,4%
El Golfo	6 [g]	30 [g]	5,500 [h]	~180 [f]	3%
Tahiti-Nui	4 [i]	50 [i]	10,500 [(*)]	~1,150 [j]	7%
Waianae	~6 [(*)]	63 [(*)]	25,000 [k]	~6,100 [l]	38%

(2001); (h) Schmincke (1998); (i) Patriat et al. (2002); (j) Hildenbrand et al. (2004); (k) Robinson and Eakins (2006); (l) Presley et al. (1997).

(*) Other values have been either calculated from other known parameters or estimated from digital elevation models and bathymetric maps.
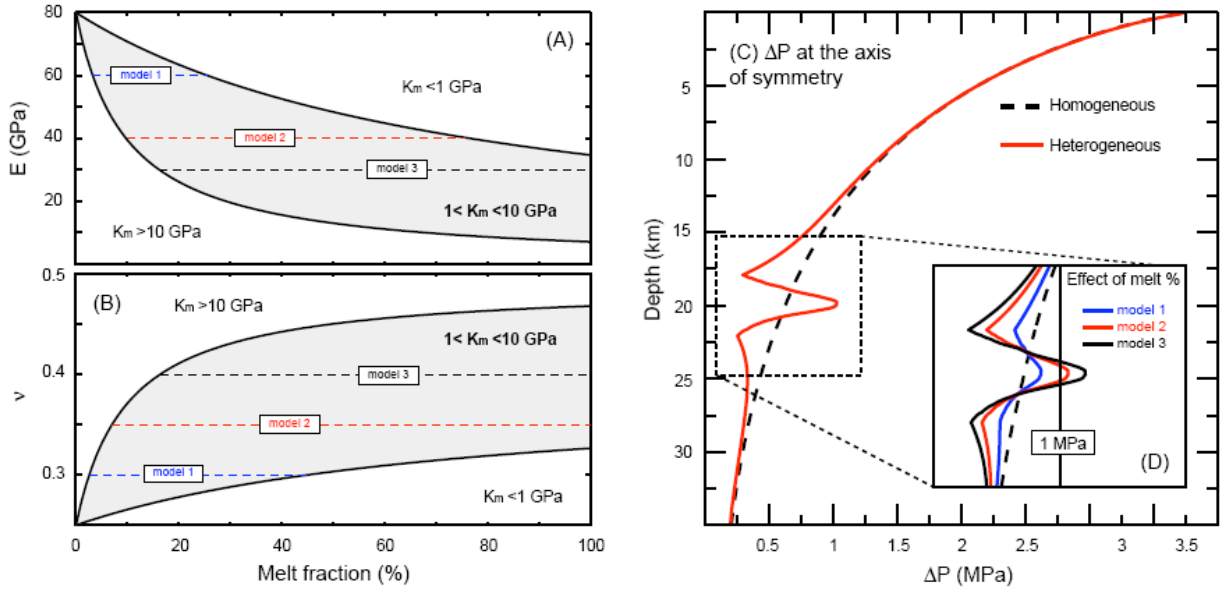

Figure DR1: Effect of melt %. (A & B) Effective elastic properties defined by Young's moduli (E) and Poisson's ratios (ν) calculated using the theoretical relationships of Walsh (1969) for melt fractions varying from 0 to 100% within the magma storage zone. See section 3 for details of the calculations. (C) Decompression amplitudes caused by the El Golfo landslide calculated on the axis of symmetry of the FE models (see Fig. 2A of the main text). Results for homogeneous (dashed line) and heterogeneous (solid red line) models are compared. (D) Melt percentage within the magma storage zone significantly affects the mechanical response of the surrounding rock. "Model 2" corresponds to the mechanical setup used for the finite element models that are presented in the main text.
Figure DR2: Effect of shape of magma storage zone on landslide-induced decompression.
