Figure DR1. Map showing MT profiles (L2, L1, and L4) sites (blue circles), main Wenchuan earthquake (large red circle, May 12, 2008, at depth of 14-19 km) and aftershocks (small red circles aftershocks with M$\geqslant$5 and pink dots show aftershocks 2$\leqslant$M<5) epicenters (Zhu et al., 2008, in main text) of the Wenchuan earthquake in Longmenshan range. The coseismic rupture along the main fault (BCf) was about 240 – 300 km in length, with maximum vertical and horizontal displacements of 6.5 m and 4.9 m respectively (Xu et al., 2009, in main text). The rupture along the east fault (PGf) was 90 km long (Xu et al., 2009, in main text). The coseismic ruptures propagated towards the northeast from the hypocenter area along the fault zone (Zhang Y et al., 2009, in main text). The rose diagrams show the geoelectric strike

25   direction at the stations plotted in yellow. The geoelectric strike direction is in a

26   NE-SW direction, in good agreement with the geologic strike of the Longmenshan.

27   YXf = Yushu-Xianshuihe fault, EKLf = East Kunlun fault, LRBf=Longriba fault,

28   MJf=Minjiang fault, LQf=Longquan fault, WMf =   Wenchuan-Maoxian fault, BCf

29   = Beichuan fault (BCf) and PGf = Penguan fault (PGf).

30

Figure DR2a. Typical apparent resistivity and phase curves at MT sites 109, 116, 127 and 139 on profile L1. These quantities are the measured data in an MT survey and described for non-experts by Simpson and Bahr (2005). The circles show the measured MT data, and the line shows the response of the inversion models in Figure 2. TE = transverse electric mode with electric current flowing parallel to the geoelectric strike direction (N45°E), and TM = transverse magnetic mode with electric current flowing perpendicular (N135°E) to the geoelectric strike direction. The curves indicate the resistivity variation along the profile which is consistent with the pseudosection in Fig.DR3a.
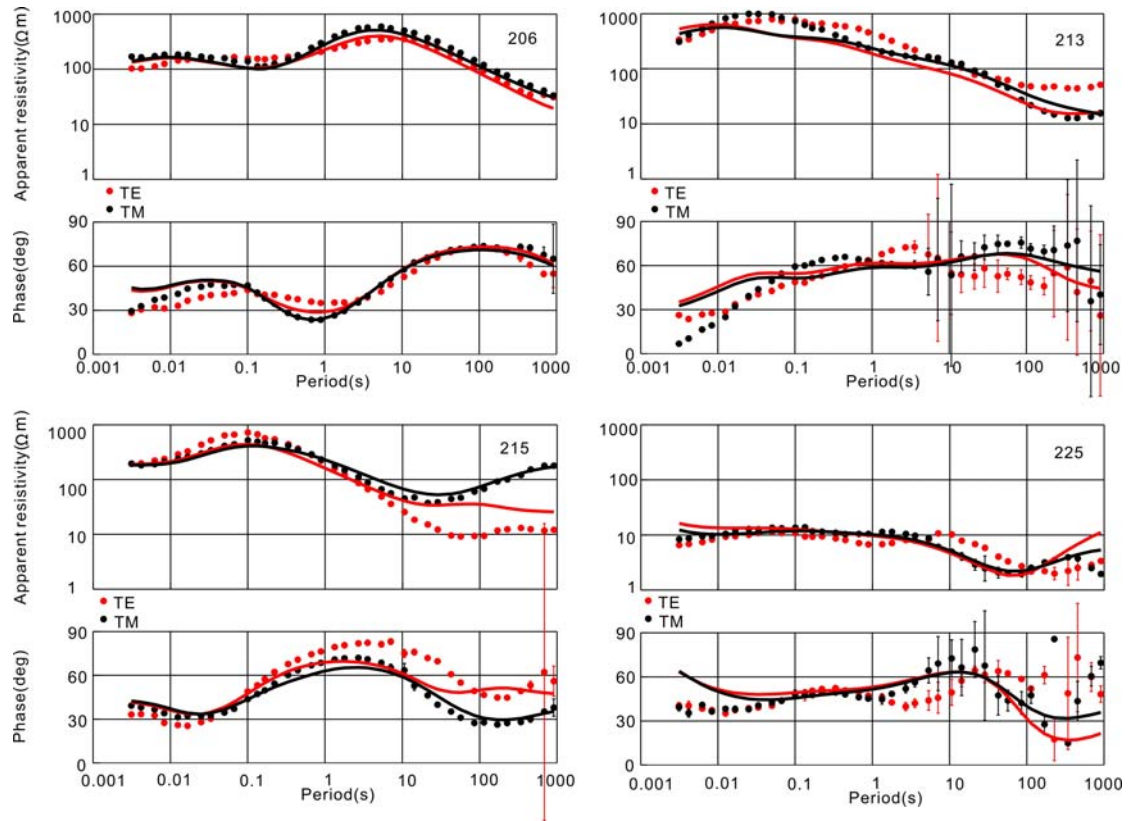

41

Figure DR2b. Apparent resistivity and phase curves for sites 206, 213, 215 and 225

on profile 2. The symbols have the same meaning as in Fig. DR2a. The curves show

the resistivity variation along the profile which is consistent with the pseudosection in
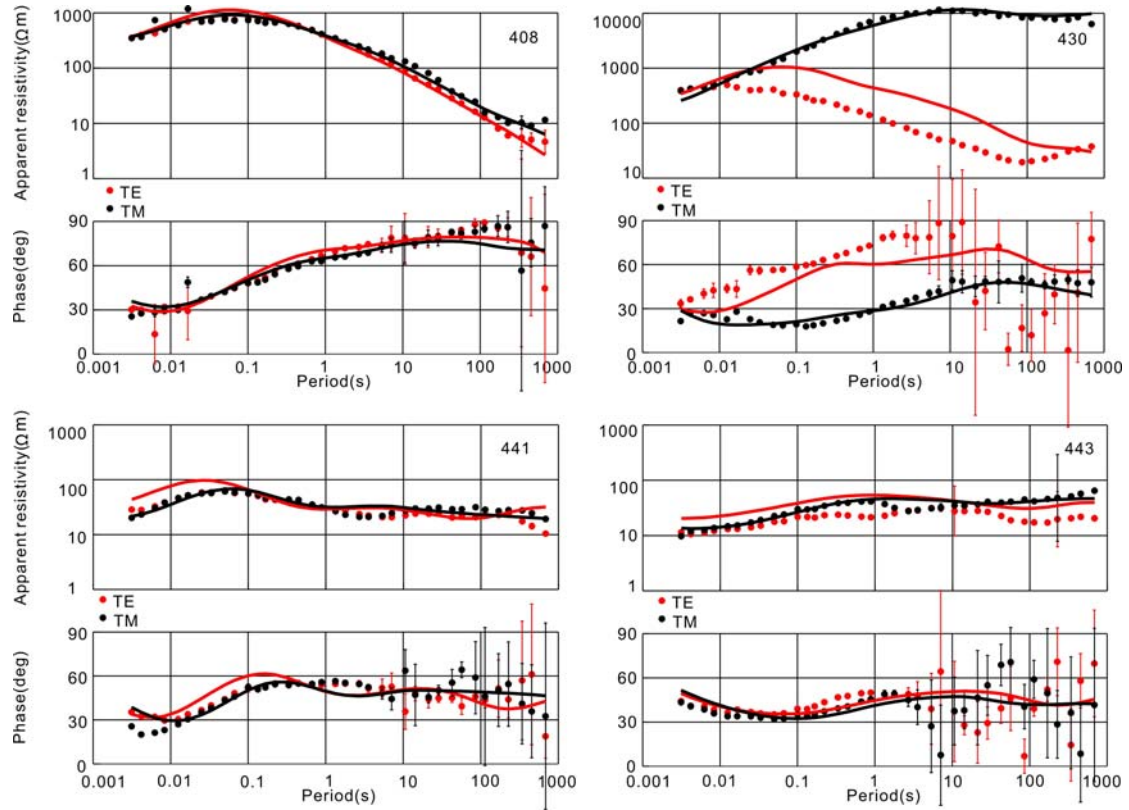

Fig.DR3b.

Figure DR2c. Apparent resistivity and phase curves for sites 408,430,441 and 443 on L4. Labeling is the same that in Fig.DR2a. The curves indicate the resistivity variation along the profile which is consistent with the pseudosection in Fig.DR3c.
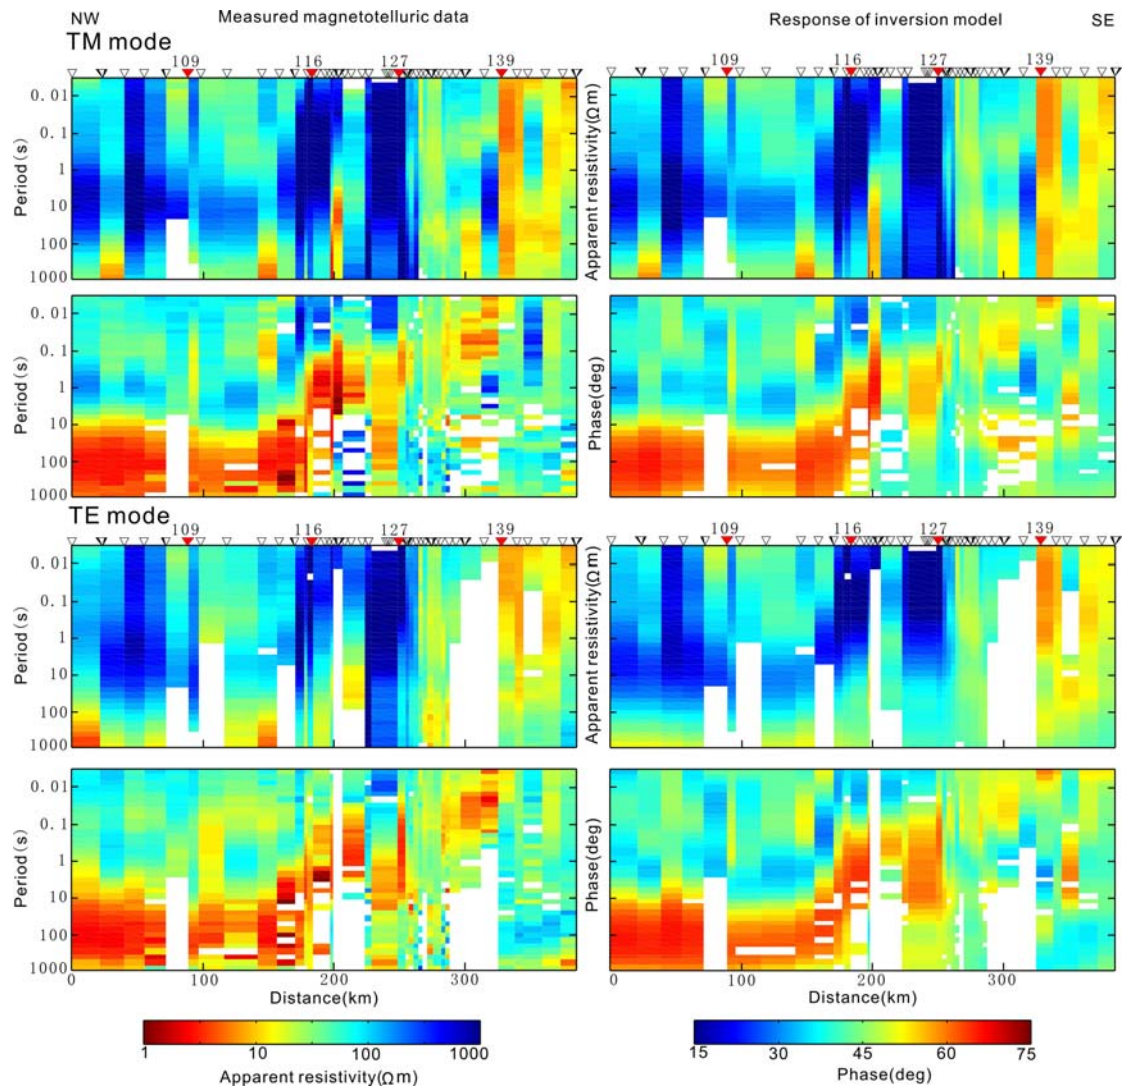

Figure DR3a. The left column shows pseudosections of the measured MT apparent resistivity and phase on profile L1. The right column shows the corresponding pseudosections of the response of the inversion model for profile L1. Note the high phase values in both the TM (top four panels) and TE (bottom four panels) modes in the period band T = 10-1000 s at a distance of 0-230 km, which are caused by the high conductive layer (HCL) beneath the Songpan-Ganzi block. The low phase values in both the TM and TE modes in the period band T = 0.01-1.0 s at distances of 230-310 km are caused by the high resistivity zone (HRB) in the inversion model in Figure 2 at the same offsets. The locations of the MT stations from Figure S2a are shown as red triangles, labeled with the station number. Note the good agreement between the measured MT data and the response of the inversion model. White regions denote data that was excluded because of noise.

Figure DR3b. The left column shows pseudo-sections of the measured MT apparent resistivity and phase data for profile L2. The right column shows corresponding pseudo-sections of the response of inversion model on profile L2. Note the high phase values in both the TM (top four panels) and TE (bottom four panels) modes in the period band T = 10-1000 s band at distances of 0-180 km, which are caused by the high conductive layer (HCL) beneath the Songpan-Ganzi block. The low phase values in both the TM and TE modes in the period band T = 0.01-1.0 s at distance of 180-260 km are caused by the high resistivity zone (HRB) in the inversion model in Figure 2 at the same offsets. The locations of the stations from Figure DR2b are shown as red triangles, labeled with the station number.
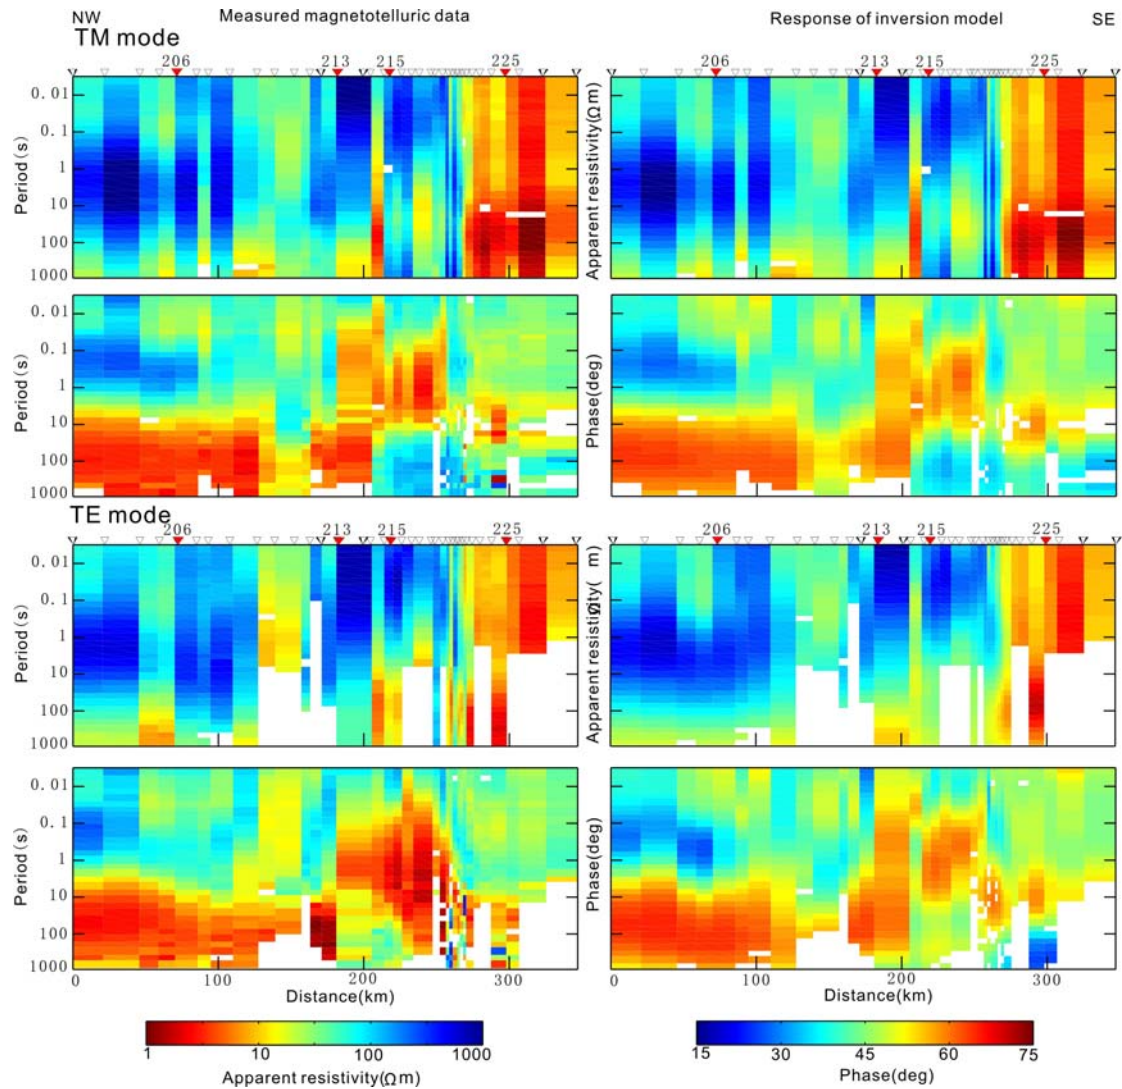

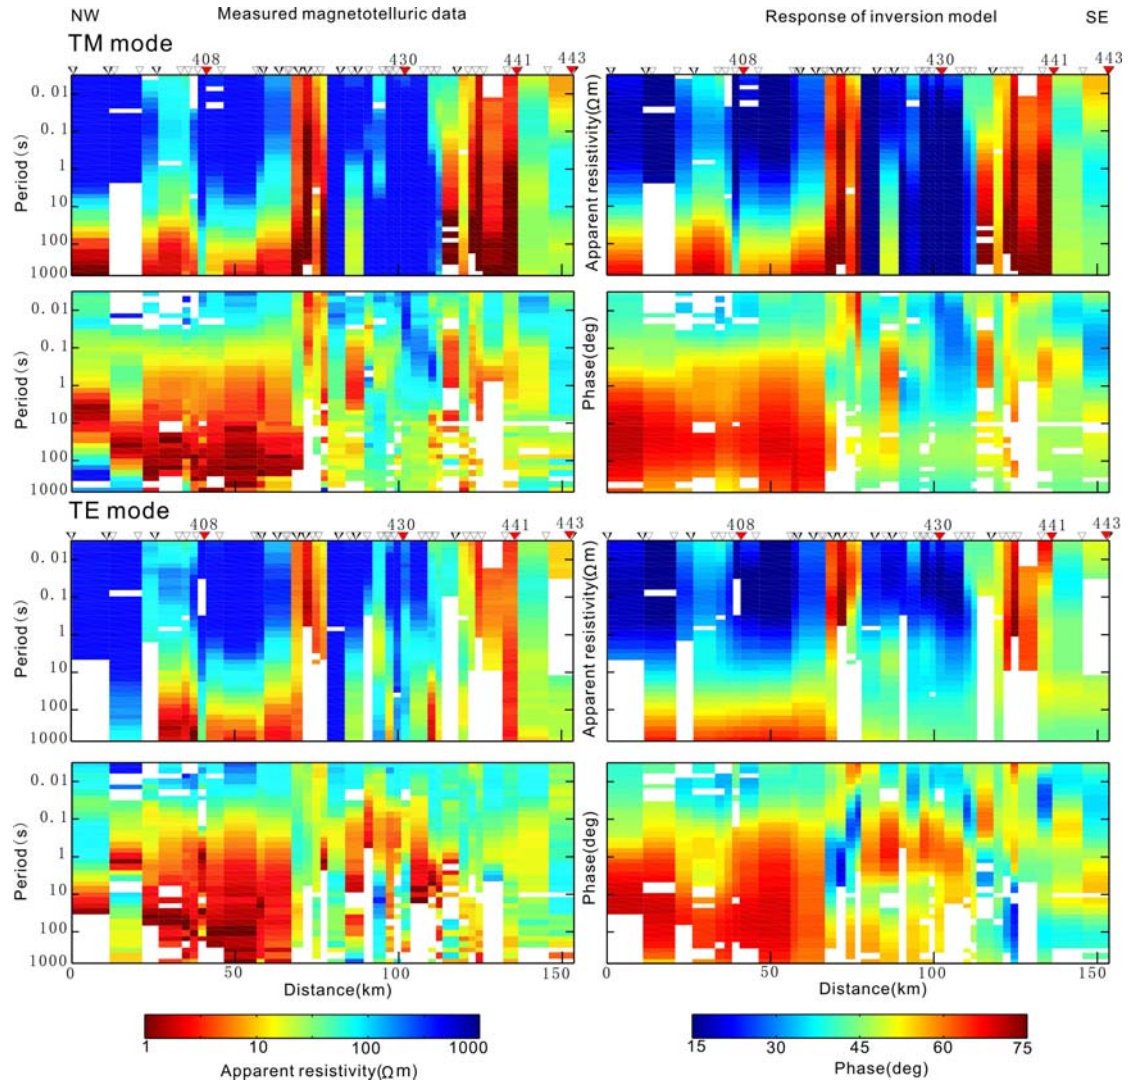

Figure DR3c. The left column shows pseudo-sections of the measured MT apparent resistivity and phase on profile L4. The right column shows corresponding pseudosections of the response of the inversion model for profile L4. Note the high phase values in both the TM (top four panels) and TE (bottom four panels) modes in the period band T = 0.1-100 s band at distances of 0-75 km, which are caused by the high conductive layer (HCL) beneath the Songpan-Ganzi block. The low phase values in both the TM and TE modes in the period band T = 0.01-1.0 s at distances of 75-120 km are caused by the high resistivity zone (HRB) in the inversion model in Figure 2 at the same offsets. The locations of stations from Figure DR2c are shown as red triangles, labeled with the station number.
Figure DR4. L-curves for models of the data from profiles L1, L2 and L4 show the trade-off between model roughness (complexity) and fitting the measured MT data. Tau=10 is considered to be the corner of the L-curve in each case, and is used for the final model of each of three profiles respectively because it is the best choice for modeling of three profiles. The inverted models show that the r.m.s misfit increased and the model became smooth when τ was increasing. Conversely, the r.m.s. misfit decreased and the model became roughner.

Table DR1. Parameters for profiles L2, L1 and L4

Profile	Length （km）	Orientation	Number of sites	Average site Spacing
L2	347	N42°W	35	9.5 km 4 km in Longmenshan
L1	400	N42°W	38	10 km 4.5 km in Longmenshan
L4	154	N42°W	34	3.7 km

Table DR2. Parameters used in the inversion and r.m.s misfit for each profiles.

Profile	Final r.m.s. misfit	Tau	Error floor				Number of cells in inversion model	
			ρ_{TE}	φ_{TE}	ρ_{TM}	φ_{TM}	Horizontal	Vertical

Item 8. Supplementary Discussion

Item 8.1) Magnetotelluric (MT) data collection in the Longmenshan

After the Wenchuan earthquake, magnetotelluric (MT) measurements were carried out along three profiles (L2, L1 and L4) that crossed the Longmenshan near the earthquake epicenter during February-May of 2009 (Table DR1 and Figure DR1). Profiles L1 and L2 passed through the most devastated areas and L1 passed directly through the epicenter of the main shock. Additional MT data were collected in October 2009 to increase the station density where rapid changes in crustal resistivity structure were observed. Complementary measurements at some sites in the epicenter region were carried out in 2011. These additional MT measurement have enhanced the MT data quality at some sites, but due to the reconstruction after the Wenchuan earthquake and the rugged topography, the site spacing and data quality at a few sites were still suboptimal in the epicentral area. Seven sets of Phoenix Geophysics V5-2000 broadband MT instruments were used in the field work including one at a permanent remote reference station. Data were recorded in the frequency band 300 -

127 0.0003 Hz. Five electromagnetic field components were recorded at each site

128 (north-south and east-west electric and magnetic fields and vertical magnetic fields).

129 Robust time series data processing was applied to the data at each site. High quality

130 data at 117 sites on three profiles were selected for subsequent analysis (Table DR1

131 and Figure DR1).

132

133 **Item 8.2) Details of 2-D inversions of the magnetotelluric data**

134 **Item 8.2.1) Geoelectric strike direction**

135 Analysis using the phase tensor technique (Caldwell et al., 2004; Cai, 2009, in this file)

136 indicates that the skew at most sites is less than 0.2 giving support for a 2D modeling

137 and inversion approach. The geoelectric strike direction is consistently around N45°E

138 for all three profiles. This agrees with the well-defined geological strike direction of

139 the Longmenshan and is perpendicular to the profile orientation as planned (Fig.DR1).

140 Therefore it is reasonable to use 2D inversion of the MT data on each profile. In this

141 frame of reference, the transverse electric (TE) mode comprises the electric field in

142 the direction N45°E and the orthogonal magnetic field. Similarly, the transverse

143 magnetic (TM) mode comprises the electric field in the direction N135°E and the

144 orthogonal magnetic field.

145

146 **Item 8.2.2) Control parameters**

147 The MT data for each profile were inverted using a conventional 2D inversion

148 algorithm (NLCG) (Rodi et al., 2001, in main text). Topography was included in the

149 inversion. The following control parameters were used in the inversions:

150 - error floor for TE phase, TM phase and TM apparent resistivity = 10%,

151 - error floor for TE apparent resistivity = 50%;

152 - trade-off parameter, $\tau = 10$

153 Additional details can be found in Table DR2. The first row of the model grid was 10

154 m in vertical extent and the thickness of subsequent rows increased with depth using a

155 geometric factor in the range 1.2 - 2.0. In the middle crust, where low-resistivity

156 layers were expected, a finer vertical grid interval was used. The size of the grid for

157   each profile is listed in Table DR2. Inversions started from a uniform halfspace. A

158   wide range of halfspace resistivity values were used for the starting model and all

159   gave essentially the same final resistivity model. The final resistivity models shown in

160   Fig. 2 were obtained using a starting halfspace resistivity of 100 Ωm. The final

161   root-mean-square (r.m.s.) misfits are listed in Table DR2. The fit is also shown in

162   pseudosection format in Figures DR3a,b,c. Note that there is generally good

163   agreement between the measured MT data and the predicted data response. The

164   robustness of the inversion was also investigated using:

165   (1) different inversion control parameters, such as different error floor and τ,

166   (2) different starting model,

167   (3) different sizes of grid etc.

168

169   **Item 8.2.3) Static shift correction**

170   Static shifts are caused by small-scale, near surface resistivity structures and cause a

171   frequency-independent offset in the apparent resistivity curves. If the static shifts are

172   ignored when the apparent resistivity is used in modeling, the resulting model may

173   contain artifacts (Simpson et al., 2005, in this file). In order to obtain a reliable

174   resistivity model for each MT profile, a static shift correction was made for selected

175   sites on three profiles (Table DR3a, b,c). Static factor fc = 1.0 means no correction

176   was applied. The static coefficients were estimated by the inversion procedure using

177   standard procedures that have been evaluated on field and synthetic data (Unsworth et

178   al., 2005, in main text). Several inversions were performed for each profile with

179   different control parameters for the static shifts. The final static shift coefficients at

180   some sites were chosen based on the data fit at the site and its neighbors. The optimal

181   static shift co-efficients are listed in table DR3a,b,c.

182

183   **Item 8.3) Interpretation**

184   Before 2008, there was an absence of earthquakes of M=7 or greater in the

185   Longmenshan range, and a 7-year quiet period without events greater than M ≥ 4.

186   This region is unsual because of the large relief difference (> 4km) across LMS range

187   and thickened crust of the SGb, yet there is a very slow shortening rate (<2mm/yr) as

188   measured by GPS data (Zhang P et al., 2009, in main text).

189   The emphasis of this paper is to define the resistivity structure of the region and use

190   this to understand the tectonics. The main results of the resistivity model derived by

191   inversion are (1) a high conductivity layer (HCL) in the crust in eastern Tibetan

192   plateau, (2) a high resistivity zone (HRB) beneath Longmenshan Range. Thus each of

193   the three profiles (L1, L2 and L4) was inverted individually using a wide range of

194   inversion parameters. As described in the main text, the inversion models for the three

195   profiles consistently indicate that a HCL occurs at a depth of about 20 km in eastern

196   Tibetan plateau and a HRB is located beneath the Longmenshan. The HRB has nearly

197   the same lateral extent as the "transition zone" (Yu et al., 2010, in main text) and is

198   located in same position as the "rupture unit" (Zhang P et al., 2009, in main text).

199   The low resistivity pathway connecting the HCL to the surface could be due to the

200   presence of interconnected aqueous fluids. The amount of fluid required can be

201   estimated using Archie's Law. Archie (1942, in this file) proposed an empirical

202   relationship for the bulk resistivity of a fluid saturated rock (ρ) given by

203    $$\rho = \rho_w \varphi^{-m}$$

204   where φ is the porosity, ρ_w is the resistivity of the pore fluid and m is the cementation

205   factor. If the fluid is distributed in cracks, then a cementation factor $m=1$ is applicable

206   corresponding to full connectivity of the fluid phase. From the inversion model for

207   profiles L1, L2 and L4 (Fig.2) the bulk resistivity of the pathway is around 10 -100

208   Ωm. With a salinity of 5 g/liter, typical of upper crust, this predicts a water resistivity

209   value of $\rho_w=1$ Ωm (Nesbitt, 1993, in this file) and Archie's Law predicts, a porosity

210   of 1-10% . The lower value reflects $m=1$ with fluids in cracks and is the most likely

211   scenario. The upper value would be quite unrealistically high. Note that the values

212   listed above are intended as order of magnitude estimates of the fluid content, and

213   reflect the lack of detailed information about crustal fluids in this area.
