

## ANALYTICAL METHODS

## Starting materials

The experiments were performed with either a mid-ocean ridge basalt (MORB) or a sample of the Central Atlantic Magmatic Province (CAMP), AN31, collected from a (Lower unit) lava flow in Morocco (table DR1). Samples were ground to less than 50 µm in size and stored in a drying oven before experiments. The AN31 was enriched in sulfur through the addition of pyrrhotite to create a bulk composition with 911 ppm S.

Table DR1. Major element and S compositions for the two starting materials used for the experiments. Oxides concentrations are expressed as wt.%, S concentration as ppm. FeO\*: total iron as FeO.

## Crystallization experiments

The rock powders for experimental samples were placed inside graphite capsules, inserted into Pt outer capsules and dried in the oven before welding. The double capsule minimizes iron loss and creates oxygen fugacity conditions below the fayalite-quartz-magnetite buffer; at these conditions almost all sulfur dissolved in the melt is sulfide ( $S^{2-}$ ; Jugo et al., 2010). Experiments were performed in a piston-cylinder using NaCl-pyrex-crushible alumina assemblies following the techniques of Baker (Baker, 2004). Experiments were simultaneously heated and pressurized to conditions above the liquidus and held at those conditions for 2 hours to ensure melt homogenization and destruction of any crystals in the starting material before cooling to subliquidus conditions where crystal growth occurred (Table DR2). Conditions were chosen to contain only a few crystals because reconnaissance experiments further below the liquidus demonstrated significant compositional heterogeneity in the pyroxenes at these conditions.

Run-product phases were analyzed for major elements on the electron microprobe using glass and mineral standards following the technique of Liu et al. (2007). In particular, basaltic glass standards VG-2 (1410 ppm S) and VG-A99 (125 ppm S) were repeatedly analyzed to ensure the accuracy of our analyses. The average major element compositions of the crystals are given in terms of their end-member components in Table DR2 and the average compositions of glasses are provided in Table DR3.

Experiment	Material	Pressure Gpa	Temperature °C	Time h	Phase assemblage and compositions

2012-38	MORB	1.2	1350/1240	2.0/20.0	glass, High-Ca px: Wo <sub>34</sub> En <sub>54</sub> Fs <sub>12</sub>	

Table DR2. Experimental conditions for sulfur partitioning experiments. High and low temperature steps of the experiments are reported, along with the duration of the experiment at the high and at the low temperature steps. Average compositions of phases are given in terms of the wollastonite, enstatite and ferrosilite components of the pyroxenes, in terms of the forsterite component for the olivine and the anorthite component for the plagioclase.

## Sulfur analyses

Sulfur in the crystals was measured by two techniques: one experiment was measured on the CAMECA IMS 1280 ion microprobe at the Northeast National Ion Microprobe Facility at Woods Hole Oceanographic Institute, and all experiments were analyzed by synchrotron X-ray fluorescence microprobe (SXRF) on beamline I18 at the Diamond synchrotron (Mosselmans et al, 2009).

The ion microprobe was operated following the techniques described in Dalou et al. (2012) with a  $\text{Cs}^+$  primary beam of 1.5 nA current; an electron gun was used to minimize surface charging. The mass resolution used was 5905, which allowed measurement of  $^{12}\text{C}$ ,  $^{19}\text{F}$ ,  $^{30}\text{Si}$ ,  $^{32}\text{S}$  and  $^{35}\text{Cl}$ ; ten cycles were acquired for each mass and then averaged. A  $30 \times 30 \mu\text{m}$  raster was used to clean the sample surface and an  $18 \times 18 \mu\text{m}$  aperture was applied to analyze the center of the rastered area. Standards used were natural and synthetic glasses (Dalou et al., 2012) and the sulfur concentration determined by the ratio of  $^{32}\text{S}$  to  $^{30}\text{Si}$ .

SXRF analyses were performed in a helium atmosphere using a 3 keV beam focused to  $6 \times 6 \mu\text{m}$  by a pair of Kirkpatrick-Baez mirrors, and the fluorescence spectra of the samples measured with a Vortex silicon drift detector. S concentrations were determined from the spectra by PyMca (Solé et al., 2007) using the silicon concentration of the minerals as the internal reference for quantification. The accuracy and precision of the analyses were tested by analysis of 4 in-house standard glasses whose S concentrations had been determined by electron microprobe and an orthopyroxene in experiment DRB2012-29 analyzed by ion microprobe. The concentration of the various glasses ranged from 70 to 142 ppm and SXRF analyses were always within 1-sigma standard deviation of the electron microprobe analyses; the average difference between the two methods was 10%. Using these standards we calculate a limit of detection of 1 ppm by two different methods (Rousseau, 2001; Goldstein et al., 2003). Based upon a relative uncertainty of 10% in our electron microprobe analyses as well as 10% uncertainty seen in our peak fitting areas we calculate through error propagation (Rousseau, 2001) an analytical uncertainty of 14% relative for samples with 6 ppm and greater. At 1.6 ppm the uncertainty in the peak fitting areas reaches 37% and the analytical uncertainty becomes 38% relative.

One orthopyroxene crystal from experiment DRB2011-29 was analyzed 6 times by ion microprobe and had an average concentration of  $0.69 \pm 0.53$  (1 sigma standard deviation) ppm S, whereas two analyses of the same orthopyroxene by SXRF yielded a concentration of  $2.9 \pm 1.8$  ppm (individual analyses yielded 4.2 and 1.6 ppm). The similarity of these concentrations suggest that both analytical techniques provide consistent results to within approximately 2 ppm, even near the calculated minimum detection limit of the SXRF.

## Experimental results

All experiments produced euhedral to subhedral crystals (Fig. DR1). In all experiments the amount of melt present during crystal growth was greater than 50%. The totals for the analyses of the glasses are all slightly low because of small amounts of water in the starting rock compositions (Table DR3). The low-calcium pyroxenes formed in experiment DRB2012-29 using the AN31 composition fall into the bronzite compositional field and contained  $0.64 \pm 0.46$  ppm S, as measured by the ion microprobe, or  $2.9 \pm 1.8$  ppm, measured by SXRF, and produced an orthopyroxene/melt  $K_D$  of either 0.001 (ion microprobe results) or 0.003 (SXRF). Because the S concentration of the orthopyroxene in this sample is so close to the detection limit of the SXRF, the ion microprobe results are preferred. At higher pressures of 1.0 and 1.2 GPa in experiments DRB2012-35 and -37 using the AN31 composition the low-calcium pyroxenes appear to be pigeonitic; these crystals contained  $29 \pm 9$  (SIMS) and  $31 \pm 9$  (SXRF) ppm S (Table DR3), producing pyroxene/melt  $K_{DS}$  of 0.026 and 0.028, respectively. The sulfur concentrations in the augites crystallized from experiments DRB2012-36 (Fig. DR1) and -38 with the MORB composition have sulfur concentrations that overlap at the 1-sigma level,  $29 \pm 7$  (SIMS) and  $25 \pm 11$  (SXRF) ppm, respectively (Table DR3). These experiments yield sulfur clinopyroxene/melt  $K_D$ s of 0.028 and 0.023. The experiments yield very similar  $K_{DS}$  between clinopyroxene and melt; combining the results for the low-calcium pyroxenes in DRB2012-35 and -37 with those of the augites in DRB2012-36 and -39 produces an average  $K_D$  of  $0.026 \pm 0.009$ . The uncertainty in all calculated partition coefficients is dominated by the standard deviations of the sulfur analyses in the crystals, but in general the pyroxene/melt  $K_{DS}$  are accurate to within  $\sim 33\%$  relative.

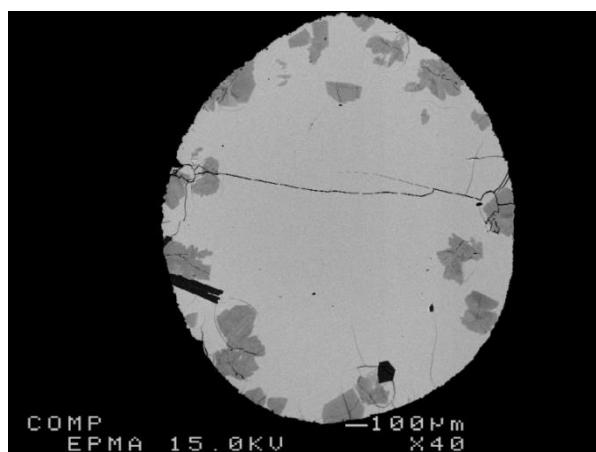

Figure DR1. Backscattered electron image of the experiment DRB2012-36. Euhedral clinopyroxene (dark gray) and plagioclase (black) phenocrysts are scattered in a (light gray) glass.

## TEM analyses

Transmission Electron Microscopy (TEM) observations on the studied samples confirm that the pyroxene crystals are homogeneous and do not contain inclusions, thus excluding the possible occurrence of “hidden” S-bearing nanophases.

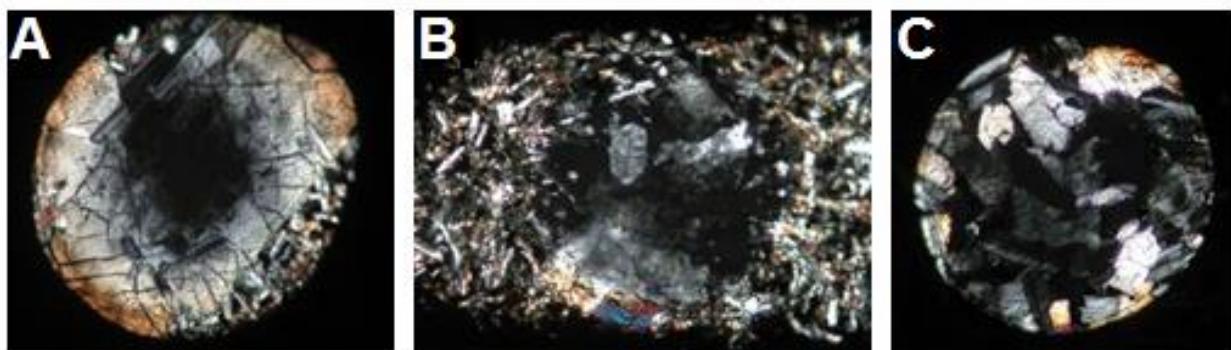

Figure DR2. Three ultra-thin TEM specimens prepared by means of ion milling with DuoMill and PIPS Ion-thinned samples; grid hole diameter of 600  $\mu\text{m}$  (polarizing microscope crossed nicols images) from sample AN510 (A-B; two clinopyroxene phenocrysts) and AN505 (C; several clinopyroxene crystals along with plagioclase and groundmass).

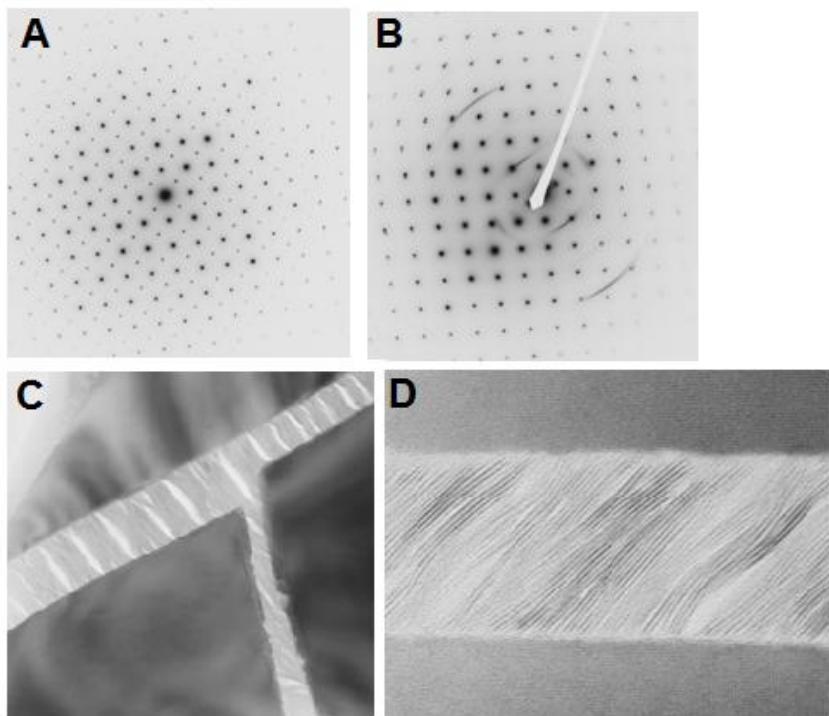

Figure DR3. Selected Area Electron Diffraction patterns reveal sharp and intense reflections (A;  $a^*b^*$  pattern of homogeneous pyroxene single-crystal). Crystal homogeneity is interrupted only by rare alteration veins, filled with poorly crystalline smectite-like material, producing weak and diffuse diffraction “arcs” (B). The thickness of alteration veins is variable (C) and, in high-resolution images, the smectite-like material shows typical wavy and irregular lattice fringes (D; 001).

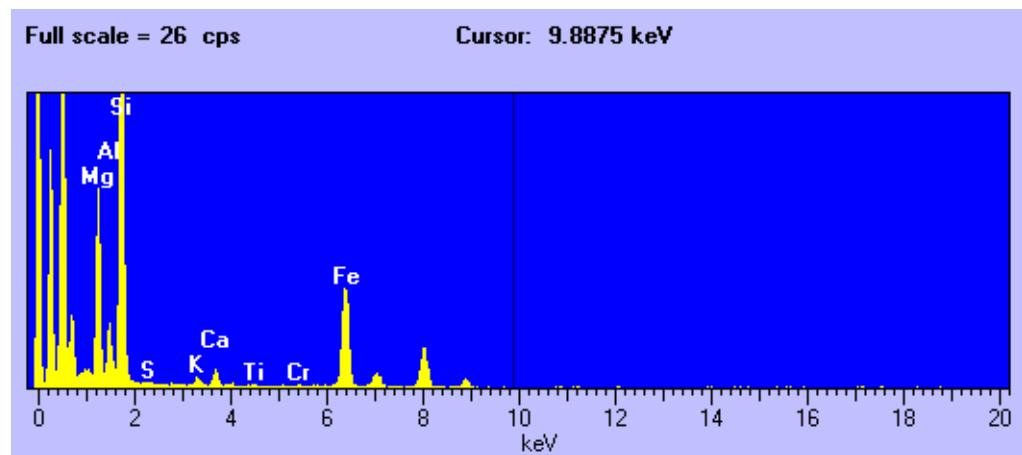

Figure DR4. Representative EDS/TEM spectrum of the Mg and Fe-rich smectite-like material within late alteration veins, obtained by large incident spot to avoid beam damage.

Table DR4 a-c. Sulfur concentrations in the clinopyroxene and those calculated for the equilibrium melt are displayed (a). Reported are also major element compositions (EMPA) for the analyzed augites (a) and major element (XRF) and Zr and Y (ICPMS) compositions for the relative whole rocks (b). Coordinates of the sampling sites are also included (c).

Mineral chemistry on pyroxenes was investigated with a CAMECA SX50 electron microprobe at the IGG-CNR of Padova, at 20 nA beam current, 20 kV acceleration voltage, 10-20 seconds counting time for the peak and 5-10 seconds for high and low backgrounds. Uncertainties on the data are 1% for major elements. The 42 clinopyroxenes from these three LIPs ( $\text{Wo}_{32-44}\text{En}_{42-55}\text{Fs}_{9-23}$ ), have non quadrilateral components ranging between 1 and 8% (aegirine up to 4.6 and jadeite up to 4.5%).

Most of the clinopyroxenes analyzed for S in this study are in equilibrium with their host rocks based upon Fe-Mg partitioning. This equilibrium supports the use of sulfur partition coefficients to calculate magmatic sulfur concentrations. The  $\text{Fe}^{2+}$  in the clinopyroxenes was calculated from  $\text{Fe}_{\text{tot}}$  after Papike et al. (1974) and a partition coefficient of  $0.25 \pm 0.05$  (Gaetani and Grove, 1998) was applied. Most samples contained augitic phenocrysts in equilibrium with the host whole-rock, demonstrating that the analyzed augites are not xenocrysts and that open-system magmatic processes (e.g. magma mixing), that can lead to non-equilibrium conditions unsuitable for the application of the clinopyroxene/melt sulfur  $K_D$ , were not dominant. The equilibrium between the clinopyroxenes and their host rocks supports application of the clinopyroxene/melt  $K_D$  based technique to estimate magmatic sulfur concentrations.
