GSA Data Repository 2016048

Rhenium-osmium isotope fractionation at the oceanic crust-mantle boundary

Alessio Sanfilippo, Tomoaki Morishita, and Ryoko Senda

Sample locations and geographical coordinates

Location of the Uraniwa Hills and Yokoniwa Rise in the southernmost portion of the Central Indian Ridge (CIR). CIR-1; CIR-2 and CIR-3 indicates different segments (see details in Morishita et al., 2015). Note that collected mantle peridotites and troctolites are spatially unrelated.

Additional Figures

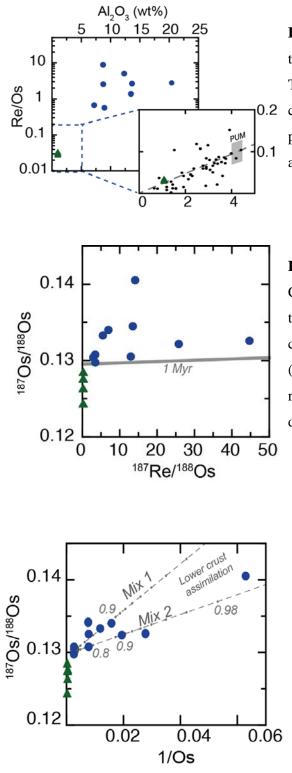

Figure DR1- Al₂O₃ versus Re/Os variations of CIRtroctolites (blue dots) and harzburgites (green triangle). The inset shows the compositions of the harzburgites compared to peridotites worldwide (green triangles) and primitive upper mantle (PUM) from Becker et al. (2006) and references therein).

Figure DR2-¹⁸⁷Re/¹⁸⁸Os versus ¹⁸⁷Os/¹⁸⁸Os variations of CIR troctolites and harzburgites. The grey line indicates the 1 Ma isochrone (initial ¹⁸⁷Os/¹⁸⁸Os 0.129) roughly corresponding to the magnetic age of the Uraniwa Hills (Okino et al., 2015). The plot clearly shows that radiogenic Os cannot have been acquired through ¹⁸⁷Re decay over time. Symbols as Fig. DR1.

Figure DR3- 1/Os versus ¹⁸⁷Os/¹⁸⁸Os ratios. Dashed grey lines represent mixing between mantle melt similar to that crystallizing the most primitive troctolite (Os =400 pg/g; ¹⁸⁷Os/¹⁸⁸Os=0.129) and altered lower oceanic crust similar to the Hole ODP 735B gabbros (Os ~10 pg/g; ¹⁸⁷Os/¹⁸⁸Os=0.17-0.145; Blusztajn et al., 2000). Symbols as Fig. DR1.

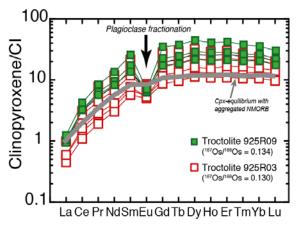

Figure DR4- REE compositions of clinopyroxenes from two troctolite samples having different Os isotopic ratios (data from Sanfilippo et al.,Lithos). The compositions of clinopyroxene at the equilibrium with NMORB were calculated through average NMORB compositions of Hofmann (1988) and clinopyroxene/basalt partition coefficents from Hart and Dunn (1993). Increasing Eu anomaly at increasing REE concentrations is due to plagioclase fractionation.

Details of analytical methods

Re-Os isotopes and Platinum Group Elements

Osmium isotopes were determined by negative thermal ionization mass spectrometry (N-TIMS) using TRITON (Thermo-Fischer Scientific). Rhenium and PGE concentrations were determined by Q-pole type inductively coupled plasma mass spectrometer (ICP-QMS; Agilent 7700s). The analytical method used for this study is identical to that reported in Ishikawa et al. (2014). In particular, Carius tube digestion method (Shirey & Walker, 1995), organic extraction method (Roybarman, & Allegre, 1995), micro-distillation method (Cohen and Waters, 1996) and anion exchange method (Pearson and Woodland, 2000) were adopted for Os, PGE and Re extraction with isotope dilution. One gram of whole-rock sample powders combined with enriched isotopes of ⁹⁹Ru, ¹⁰⁵Pd, ¹⁸⁵Re, ¹⁹¹Ir, ¹⁹⁰Os, and ¹⁹⁶Pt solutions and inverse aqua regia solution (total 10 mL) were sealed in Pyrex glass tubes. The tubes were heated in an oven at 240°C for 72 hours. After heating, carbon tetra chloride was used for extraction of Os from the acid solution three times. Then the Os was back-extracted into HBr and purified by micro-distillation. Purification of Re and other PGE was accomplished by two kinds of anion-exchange column and solvent extraction using Nbenzoyl-N-phenylhydroxylamine. Measurements of Os isotopes were done by negative thermal ionization mass spectrometry (N-TIMS) using TRITON (Thermo-Fischer Scientific). Peak jumping method using an axial secondary electron multiplier (SEM) for Os. Analyses of DROsS osmium standard solution (0.2-0.4ng) measured by SEM peak jumping gave 187 Os/ 188 Os = 0.16096 ± 19 (2SD, n=8). Rhenium and other PGE isotopes were measured by the Q-pole type inductively coupled plasma mass spectrometer (ICP-QMS, Agilent 7700 s), installed in JAMSTEC. Total procedure blanks were 0.97 ± 0.28 pg Os, 0.39 ± 0.12 pg Re, 1.87 ± 0.28 pg Ru, 68.9 ± 8.4 pg Pd, 0.61 ± 0.92 pg Ir, and 202.5 ± 63.1 pg Pt respectively (n=7, 1 standard deviation (SD)). The blank correction for each samples are 0.02~1.6% Ir, 0.02~6.0% Ru, 1.7~60% Pt, and 2.1~54% Pd, respectively, Os and Re data are in the Table DR1. Average of Os isotope ratios of procedural blanks was ${}^{187}\text{Os}/{}^{188}\text{Os} = 0.141 \pm 0.025$.

As sulfides are the main carrier of PGE, it has been argued that bulk-rock Re-Os isotope compositions of peridotites are affected by the heterogeneous distribution of different sulfides populations at a sample scale (see for instance Alard et al., 2005; Harvey et al., 2006; 2011). To evaluate this possibility, we performed duplicate analysis on two different sample splits for four samples. These duplicates have Re-Os isotopic ratios almost undistinguishable from the original determinations, although they testify a local variability in terms of absolute PGE concentrations (see Table DR1). In addition we analyzed reference materials with our method in parallel to the unknowns. These analyses are furnished in Table DR2 where they are compared with literature data.

Bulk rock major and trace elements

Bulk-rock major and trace elements analyses were determined at JAMSTEC. The major

element compositions were measured by X-ray fluorescence spectrometer (XRF), following the

fused glass bead method described in detail by Tani et al. (2006). Trace elements compositions

were determined by inductively coupled plasma-mass spectrometry (ICP-MS) using Agilent

7500ce. Sample powders (~50 g) were digested by HF and HClO₄ using the method reported in

Nakamura and Chang (2007) and Senda et al. (2014). Compositons are reported in Table DR1.

Reactive crystallization model

The reactive crystallization model (Fig. 1) predicts the Os composition of a mantle derived melt evolving through the preferential assimilation of interstitial radiogenic sulfides and synchronous fractionation of magmatic sulphides (see also Sen et al., 2011). Given the dependence of PGE compositions on the amount of sulfides accumulated in the silicate matrix, this model is used to verify whether increasing ¹⁸⁷Os/¹⁸⁸Os ratios can be acquired by melt-mantle interaction, rather than reproduce the exact Os versus ¹⁸⁷Os/¹⁸⁸Os correlation of our troctolites.

Experimental studies show that Os is mostly partitioned between crystalline sulphides and molten sulphide melt, where immiscible sulfide melt droplets are physically entrained in silicate melt (Ballhaus et al., 2006;Bockrath et al., 2004). Using D_{Os} sulphide melt/silicate melt of 4.8 x10⁴ and initial Os composition of (500 pg/g) from Burton et al. (2002) we calculated the Os versus ¹⁸⁷Os/¹⁸⁸Os composition of the melt produced at each step of the reaction. At each step, the initial melt interacts with 1 wt% of peridotite, crystallizing the same amount of silicate phases (Ma/Mc ~1), in agreement with thermodynamic calculations on melt-mantle reactions (see Kelemen et al., 1997; Collier and Kelemen, 2010) and with our previous study on Uraniwa troctolites (Sanfilippo et al., 2015). Considering a mean ¹⁸⁷Os/¹⁸⁸Os ratios of 0.120 and 0.150 for unradiogenic and radiogenic sulfides in AP (Alard et al., 2005; Harvey et al., 2006; Warren and Shirey, 2012) and supposing that sulfides constitute ~0.05 wt% of the rock (Luguet et al., 2003), we assume that radiogenic sulfides of the reacted peridotite ($^{187}Os/^{188}Os=0.1265$) constitute ~0.01 wt% of the rock mass. Hence, each step of interaction corresponds to assimilation of ~0.0001% interstitial radiogenic sulfides, followed by the same amount of sulfide segregation. Table DR3 reports the initial parameters and the compositions of the reacting melts. Here follows a brief explanation of the equations used.

6

Interstitial sulphides assimilation:

- The *Os* concentration is given by the mixture between the two end-members (*A*, initial melts and *B*, radiogenic sulphides) calculated as weighted average of the two components.
- The ¹⁸⁷Os/¹⁸⁸Os ratio is calculated based on mixing equations in Faure (1998). Equation 1 describes the variation in the ¹⁸⁷Os/¹⁸⁸Os ratio to be expected in a mixture generated by combining various proportions of Os from two different end-members with different ¹⁸⁷Os/¹⁸⁸Os ratios:

$$\left(\frac{1870s}{1880s}\right)mix = \frac{a}{[0s]mix} + b$$
 (Eq. 1)

The slope of the mixing line is calculated from equation 2:

$$a = \frac{[Os]A*[Os]B*\{\left(\frac{1870s}{1880s}\right)B - \left(\frac{1870s}{1880s}\right)A\}}{[Os]A - [Os]B}$$
(Eq. 2)

and the y-intercept from Equation 3:

$$b = \frac{[OS]A*\left(\frac{1870S}{1880S}\right)A - [OS]B*\left(\frac{1870S}{1880S}\right)B - [OS]A - [OS]B}{[OS]A - [OS]B}$$
(Eq. 3)

Magmatic sulphides fractionation:

- The *Os* concentration of the reacting melt is calculated from Rayleigh equation (Eq. 4) using initial melt *Os* composition and the extent sulphide fractionation (*F*) at each step of the *Interstitial Sulphides Assimilation* process.

$$Os (react. melt) = Os * \frac{1}{(1-F)*(1-D)+D}$$
 (Eq. 4)
