What do earthquakes reveal about ambient shear stresses in the upper crust?

(by Guy Simpson)

The Supplementary material provided here includes the following items:

- Description of Mechanical model

- Description of Monte Carlo model

- Table DR1

- Figs. DR1-DR7

Description of Mechanical model

The mechanical model is based on quasi-static force equilibrium and mass balance of a viscoelastic fluid subjected to plane strain deformation and gravity (Simpson, 2015). The model considers a two-dimensional vertical depth section (180 km wide x 60 km deep) containing a single inclined planar fault discontinuity embedded within an elastic material (with a shear modulus of 30×10^9 Pa and Poisson's ratio of 0.25) that is underlain by a high viscosity (10^{19} Pa s) Maxwell viscoelastic material (Fig. DR1). The model faults are assumed to be optimally oriented for frictional sliding. Thus, for a typical background friction coefficient of 0.577, the reverse faults have dips of 30°, whereas the normal faults have dips of 60°. The initial differential stresses in the upper layer are computed assuming that

20 faults are critically stressed for frictional sliding. The thickness of the faulted upper

21 elastic layer is varied between 5 and 30 km. The lower viscoelastic layer is initially

22 assumed to have zero differential stresses. Models are loaded by imposing constant

23 horizontal velocities (of 50 mm/yr) at the lateral boundaries. The upper boundary is

24 a free surface while all other boundaries are free slip. Solutions to the system of

25 partial differential equations were computed using the continuous Galerkin Finite

26 Element Method using 7-node triangles for velocities and 3 nodes for pressures.

27   The fault in each model exhibits stick-slip behavior that is governed by rate-

28 and state-friction. Fault friction is calculated from the lab-derived law (Noda et al.,

29 2009)

30 $$\mu = a \ln\left(\frac{v}{v_o}\right) + \theta \qquad (3)$$

31 where v is the slip velocity, and θ is a state variable that is computed by solving

32 $$\frac{\partial \theta}{\partial t} = -\frac{v}{D_c}(\mu - \mu_{ss}) \qquad (4)$$

33 with the steady state friction value

34 $$\mu_{ss} = \mu_o + (a - b)\ln\left(\frac{v}{v_o}\right) \qquad (5)$$

35   Here μ_o is a reference friction coefficient for steady sliding at velocity v_o, a and b

36   are dimensionless parameters characterizing the direct and state evolution effects,

37   respectively, and D_c is the state evolution distance. In this slip-law formulation I

38   set the shear stress on the fault (computed by solving the quasi-static viscoelastic

39   problem) to the fault strength, modified to account for radiation damping, i.e.,

$$\tau = \mu\,\tilde{\sigma}_n + \frac{G}{2c_s}v \qquad (6)$$

41   where τ and $\tilde{\sigma}_n$ are the shear and effective normal stresses resolved on the fault, G

42   is the shear modulus, c_s is the shear wave speed and μ is the variable friction

43   coefficient given by equation (3). This nonlinear equation (i.e., 6) is solved for the

44   sliding velocity that is then imposed on the fault using the split-node technique

45   (Melosh and Raefsky, 1981).

46   Although most calculations presented are based on a 'standard' rate- and

47   state-friction law (i.e., equations 3-5) I also carried out simulations incorporating

48   additional dramatic weakening at seismic slip rates, which has been demonstrated

49   in laboratory friction experiments (e.g., Di Toro et al., 2011; Nielsen et al., 2016).

50   Enhanced weakening was introduced (after Noda et al., 2009) by replacing

51   equation (5) with

$$\mu_{LV} = \mu_o + (a - b)\ln\left(\frac{v}{v_o}\right) \qquad (7)$$

53   and

$$\mu_{ss} = \begin{cases} \mu_{LV} & \text{if} \quad v \leq v_w \\ \mu_w + (\mu_{LV} - \mu_w)(v_w/v) & \text{if} \quad v > v_w \end{cases} \qquad (8)$$

55   Here, μ_{LV} is the conventional low velocity steady-state friction coefficient, a and b

56   are the standard rate and state parameters, respectively, μ_o is the friction

57   coefficient at the reference sliding velocity v_o, v_w is the sliding velocity at the

58   onset of enhanced weakening and μ_w is the fully weakened friction coefficient

59   (that may be close to 0.2).

60   Unless stated otherwise, calculations presented here were performed with the

61   following parameter values: μ_o=0.6, v_o =10^{-6} m/s, $a = 0.015$, c_s=3 km/s, $D_c = 0.07$

62   m, $\theta_{initial} = 0.5$. The state parameter b is taken to be 0.02 until 2 km above the base

63   of the fault when it is assumed to decrease linearly with depth to 0 (Fig. DR1C).

64   This implies that the lower portion of each fault exhibits velocity strengthening

65   behavior (a-b>0) whereas the upper part is velocity weakening (since a-b<0).

66   These parameter values are similar to those used in other earthquake modeling

67   studies. A friction coefficient of 0.6 is chosen to be consistent with Byerlee's law

68   (Byerlee, 1978).

69   In most simulations presented, elastic waves are neglected but inertial effects

70   are considered via the radiation damping approximation (Rice, 1993), making the

71 model quasi-dynamic. Additional simulations were performed incorporating full

72 inertia (e.g., see results in Figs. DR2-4). Fluid pressures are not explicitly

73 considered but are incorporated by modifying the initial effective normal stresses.

74 Dynamic effects related coseismic temperature variation are not explicitly treated

75 (e.g., see Noda and Lapusta, 2010) but were investigated indirectly by

76 incorporating enhanced dynamic friction weakening. Off-fault damage is not

77 considered in the simulations, which is considered reasonable since it appears to

78 have a minor influence on earthquake properties such as the total coseismic slip

79 (Thomas et al., 2017).

80 The model faults exhibit a natural transition from slow slip during the

81 interseismic period to rapid slip during 'earthquakes'. This threshold-type behavior

82 requires adaptive time stepping. The time step is roughly proportional to D_c/v

83 (where D_c is the slip weakening distance and v is the computed slip velocity), so it

84 varies by approximately 10 orders of magnitude between the interseismic and

85 coseismic periods. Calculations performed with excessively large time steps

86 exhibit oscillatory slip velocities (Fig. DR7A) that disappear when the time step is

87 sufficiently reduced (cf. Figs. DR7B and DR7C).

88 The calculations also require a highly resolved spatial grid in order to

89 achieve accurate and stable solutions. The element size for resolved solutions is

90 controlled by the parameter grouping $2GD_c/\pi\tilde{\sigma}_n(b-a)$ (see Rice 1993). Although

91   this limit implies exceedingly small elements, I follow a common approach (Rice

92   1993) by assigning artificially large values to D_c (usually 0.07 m) to relax the

93   element size limit. I also take advantage of an unstructured triangular mesh (Fig.

94   DR1A) that enables relatively small elements (on the order of 100 m long) to be

95   used along the fault whereas the elements elsewhere can be much larger (i.e., by at

96   least one order of magnitude).

97   **Description of Monte Carlo model**

98   The static stress drop of earthquakes in the quasi-dynamic Finite Element

99   models is well described by the empirical relation

100
$$\Delta\tau = \left(1 - \frac{\mu_d}{\mu_s}\right)\bar{\tau} \tag{9}$$

101   where $\Delta\tau$ is the average static stress drop associated with an earthquake, $\bar{\tau}$ is the

102   average shear stress on the fault, μ_d is the kinematic friction coefficient during

103   rupture and μ_s is the static friction coefficient typical of the interseismic period

104   (Fig. DR4). The stress drop is linked to the mean coseismic slip via the well known

105   relation from static crack theory (Scholz, 2002):

106
$$\bar{u} = \frac{\Delta\tau\, W}{G\, C} \tag{10}$$

107   where G is the shear modulus, W is the down-dip rupture width and $C = 4(\lambda +$

108    $G)/\pi(\lambda + G)$ where λ is the Lamé constant. To evaluate whether one can expect to

109   observe notable differences in stress drops and slip magnitudes for earthquakes

110   occurring at different depths and in different tectonic stress regimes when the

111   frictional properties also vary, I adopted a Monte Carlo approach , repeatedly

112   solving (9) and (10) for a large number of events (at least 100,000) while randomly

113   varying the tectonic stress regime (i.e., compressive versus extensive), hypocenter

114   depth (which controls the average shear stress), and the static and dynamic friction

115   coefficients within reasonable limits. Faults are assumed to be governed by

116   Andersonian faulting theory. Accordingly, the average vertical stress on the fault is

117   taken as the lithostatic stress at the rupture mid-depth H (i.e., $\rho g H$), while the

118   horizontal stress is that required to initiate frictional sliding, i.e., $\bar{\tau} = \mu_s \tilde{\sigma}_n$ where

119    $\tilde{\sigma}_n$ is the effective normal stress:

120
$$\tilde{\sigma}_n = \frac{(\sigma_1 + \sigma_3)}{2} - p_f + \frac{(\sigma_1 - \sigma_3)}{2} \cos 2\vartheta$$

121   and $\bar{\tau}$ is the average shear stress on the fault:

122
$$\bar{\tau} = \frac{(\sigma_1 - \sigma_3)}{2} \sin 2\vartheta$$

123   Here σ_1, σ_3, p_f and are the maximum and minimum principal stresses and fluid

124   pressure at H, μ_s is the static friction coefficient and $\tan \vartheta = \mp 1/\mu_s$. For reverse

125   faulting, the vertical and horizontal stresses are assumed to be the minimum and

126   maximum principal stresses, respectively, whereas the converse is true for normal

127   faulting.

128   Parameters values used for the calculations were chosen to be physically

129   realistic but were fine-tuned by fitting the computed stress drop distribution to

130   natural stress drop data from Allmann and Schearer (2009). Parameters maintained

131   constant were the rock density (ρ =2800 kg m^{-3}), fluid density (ρ_f =1000 kg m^{-3})

132   and shear modulus (G=30 GPa). The rupture mid-depth (H) was chosen from a

133   normal distribution with a mean of 15 km and a standard deviation of 5 km. The

134   static friction coefficient μ_s was chosen from a normal distribution with a mean of

135   0.7 and a standard deviation of 0.1. Faults were randomly chosen to be either

136   reverse or normal from a uniform distribution. Good fits with data were obtained,

137   which suggests that the parameters are reasonable, though equally good fits can be

138   obtained with other parameter combinations.

139   I considered two different end-member fault stress scenarios. In the first

140   (Fig. 3A of main text), fluid pressures were assumed to be hydrostatic, implying

141   that faults operate at relatively high shear stresses. In the second case (Fig. 3B), I

142   assumed that the minimum effective principal stress cannot exceed a constant

143   value $\tilde{\sigma}_c$. The values for $\tilde{\sigma}_c$ were chosen from a Weibull distribution, with scale

144   and shape parameters of 20 MPa and 1.7 MPa, respectively. This implies large

145   fluid overpressures at depth, which leads to low and constant shear stresses below

146   an upper 'normally' pressured regime (Fig. DR7). For both scenarios presented in

147   Figure 3 (main text), the friction drop $\Delta\mu$ ($=\mu_s - \mu_d$) was chosen from a log-

148   normal distribution with means of 0.015 (case 1) and 0.014 (case 2) and standard

149   deviations of 0.0144 (case 1) and 0.012 (case 2).

150

Table DR1: Rupture properties of large crustal earthquakes (M_w=moment magnitude, L =

rupture length, W = down-dip rupture width, D = mean coseismic slip amplitude). Only

earthquakes with W≤40 km are studied. Except for the last three entries, the data are from the

finite-source rupture model database (SRCMOD; Mai, 2016). The last three earthquake entries

are from the following references: Borah Peak (Stein and Barrientos, 1985), Kozani Grevena

(Clark et al., 1997), Yutian County (Furuya and Yasuda, 2011). The data are plotted in Fig. 4

(main text).

Figure DR1 A-C: Typical mode setup for earthquake simulation on a reverse fault. A: Planar

reverse fault embedded in an elastic layer that overlies a viscoelastic layer, subjected to remote

loading and gravity. Triangles are finite elements on which the solution is computed. B: Initial

effective stress state versus depth in the upper part of the model. C: Variation of the rate- and

state-friction parameters *a* and *b* on the fault.

167

168

Figure DR2 A-B: Mean slip versus time (A) and mean shear stress versus time (B) on reverse

and normal faults in numerical experiments incorporating full inertia, with and without enhanced

dynamic weakening (μ_w =0.2, $v_w = 0.1$ m/s, see equation 8 above). The average slip rate on the

normal fault is greater than on the reverse fault because the former has a larger dip.

174

Figure DR3: Computed mean slip versus time on a normal fault with and without enhanced

dynamic weakening and full inertia (FD = fully dynamic, QD = quasi-dynamic). Simulations

with enhanced weakening were calculated with μ_w =0.2, v_w = 0.1 m/s (see equation 8 above).

Otherwise, classic rate-and state-dependent friction was assumed, using the parameters listed
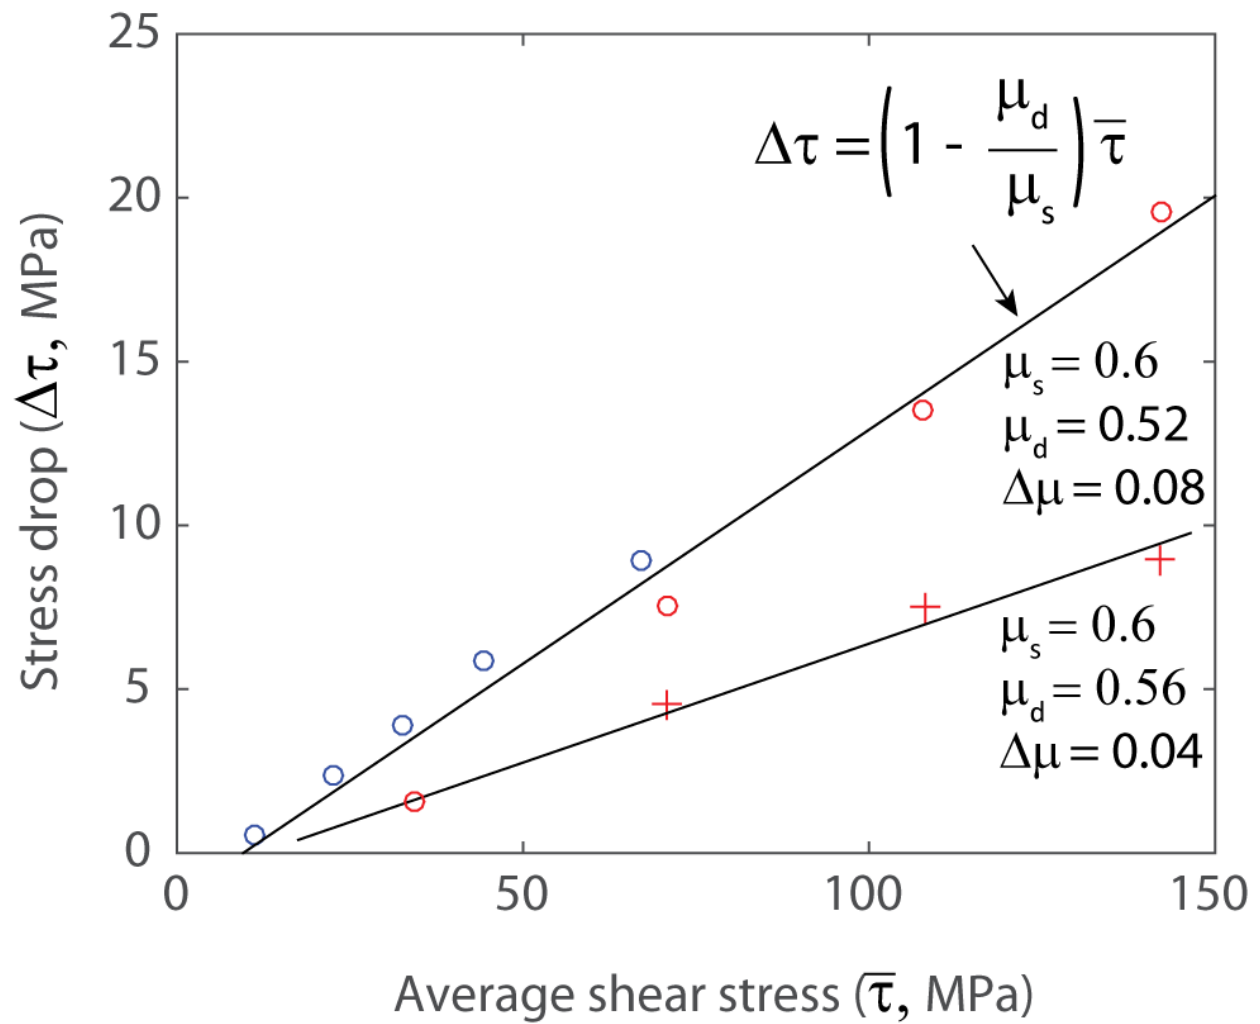

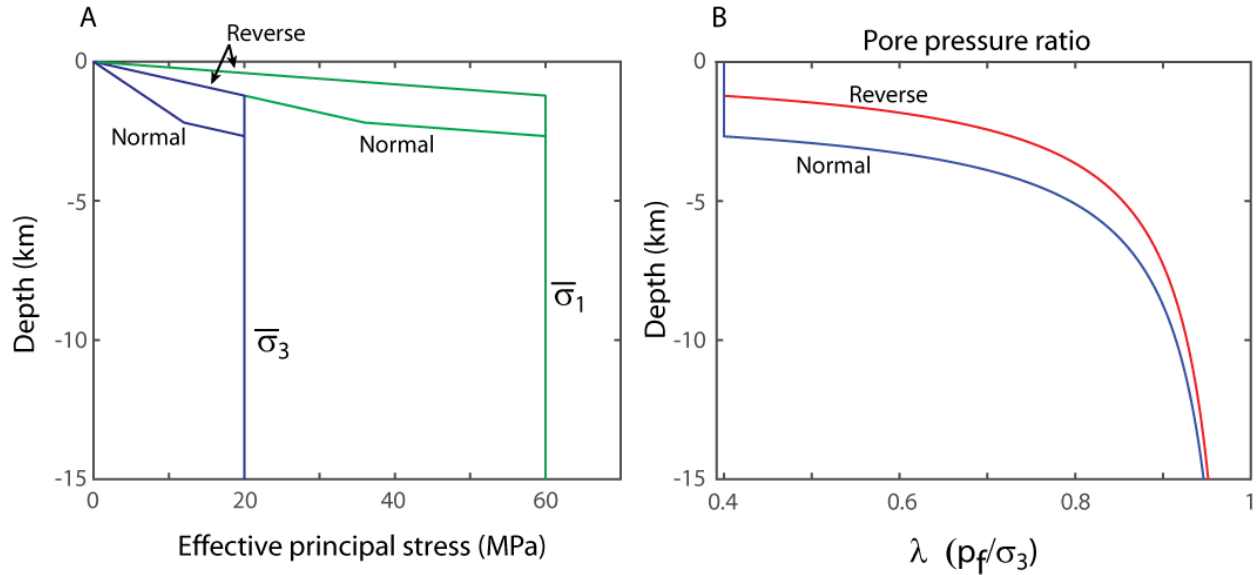

above.

180

Figure DR4 A-B: Comparison of the slip rate versus distance along the fault for simulations

using the quasi-dynamic approximation (A) and full inertia (B). In both cases, the ruptures are on

reverse faults with identical material properties. The rupture in the quasi-dynamic simulation

propagates as a crack, while that in the simulation with full inertia propagates as a slip pulse.

Even so, the simulations exhibiting pulse-like behavior still show larger slips on reverse faults

than normal faults, when ambient stress levels are high (see Fig DR2).

189

Figure with y-axis "Stress drop ($\Delta\tau$, MPa)" ranging 0 to 25, x-axis "Average shear stress ($\overline{\tau}$, MPa)" ranging 0 to 150.

$$\Delta\tau = \left(1 - \frac{\mu_d}{\mu_s}\right)\overline{\tau}$$

$\mu_s = 0.6$
$\mu_d = 0.52$
$\Delta\mu = 0.08$

$\mu_s = 0.6$
$\mu_d = 0.56$
$\Delta\mu = 0.04$

190

194

195

196

197   **Figure DR6 A-B:** Illustration of initial effective principal stress state in models considering fluid

198   overpressures. The upper part of the crust is assumed to have hydrostatic fluid pressures whereas

199   the underlying rocks have overpressures governed by the condition $\tilde{\sigma}_3 = \tilde{\sigma}_c$ where $\tilde{\sigma}_c$ is a

200   constant (in this case 20 MPa). Stresses are defined by Andersonian faulting theory with a

201   friction coefficient of 0.6 and a rock density of 2800 kg/m^3. A: Variation of the effective

202   principal stresses with depth for reverse and normal faulting stress regimes. B: Variation in the

203   pore pressure ratio (defined here as the ratio between the fluid pressure and the total minimum

204   principal stress) with depth for reverse and normal fault regimes.
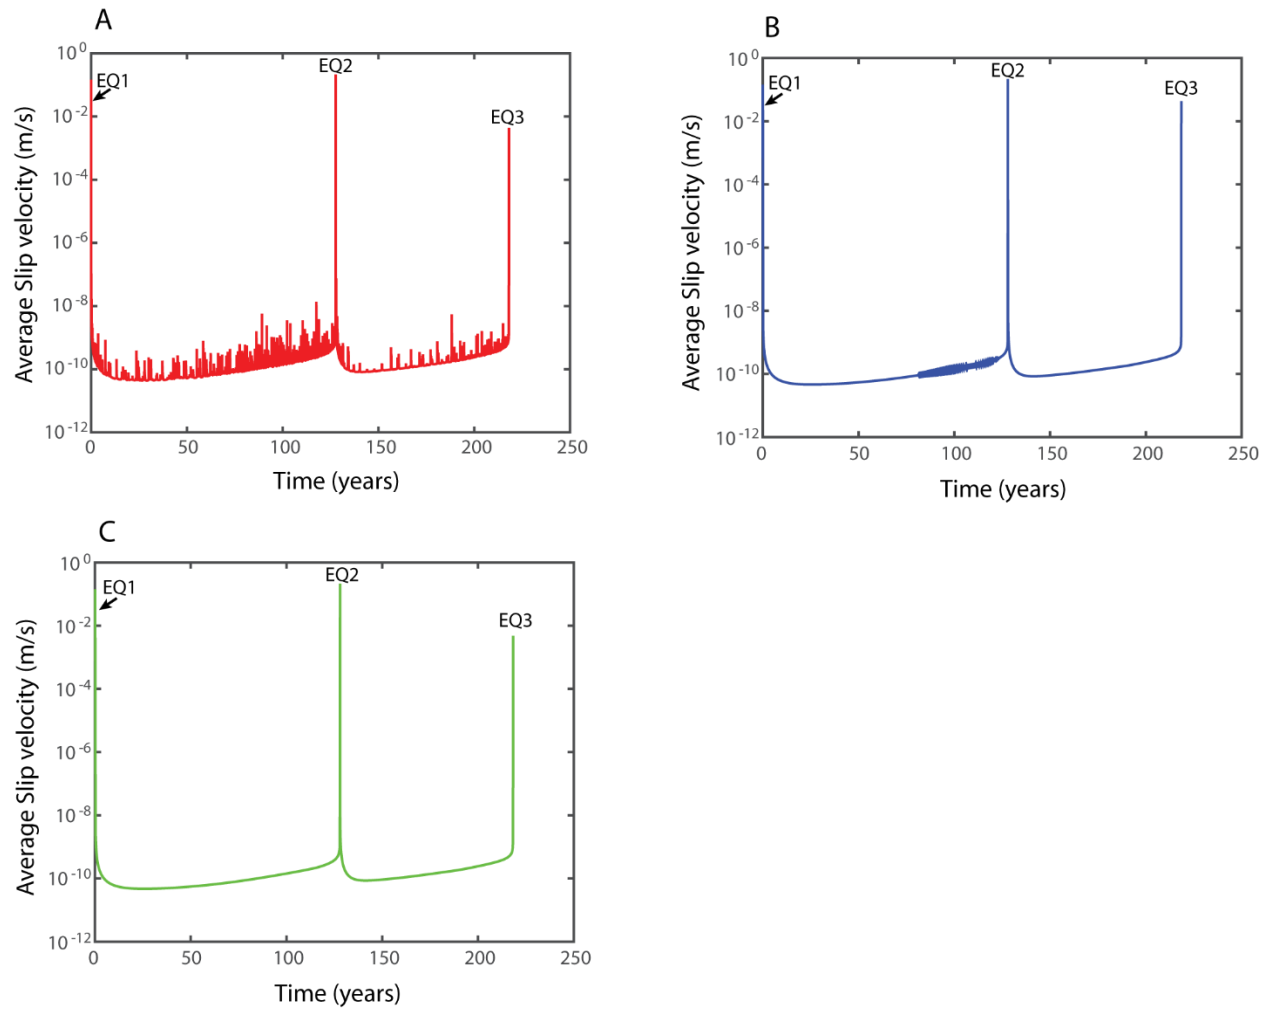

205

206

Figure DR7 A-C: Illustration of time scale resolution in quasi-dynamic numerical experiments.

Plots show the mean slip velocity on the fault versus time for quasi-dynamic simulations

performed with different temporal resolutions. The excessively large time step in (A) leads to

numerical oscillations. Reducing the time step by a factor of two reduces the oscillations (B),

which disappear entirely when the time step is decreased another two times (C).
