24   Notes:

25   *Our observations of the highland drainage network are based on morphometric analysis

26   over a 12 m DEM acquired from TanDEM-X (Wessel, 2016).

27   [‡]The basin name refers to the transect between the channel and the escarpment. In

28   reversed channels, the transect is a waterfall, and the name represents the east draining

29   basin. When there is no reversal, the transect is a saddle, and its name represents the two

30   basins that diverge from it.

31   [**]Distance along flow from the windgap to the waterfall.

32   [#]Distance along flow from the waterfall to a line that represents the regional escarpment

33   cliff.

34   [##] see methods DR1.

35   [###] see methods DR1.

36 † sites that were surveyed in the field.

37 ‡Measured from a drone created DEM. Reported errors are smaller than TanDEM-X

38 data: the horizontal error is 0.1m and the vertical error is 0.06m.

39 § A field survey reveals that here, the reversed channel is not associated with incision into

40 valley fill, but it was likely formed by a natural dam in the antecedent channel. More

41 specifically, the windgap in this location is associated with coarse deposits at the outlet of

42 a side tributary, these deposits are likely associated with debris flow deposits that

43 dammed the channel and induced its reversal.

44 §§Nine meters of alluvial coating sitting on the waterfall.

45

46

47

48   (2) FIELD AREA DR1.

49   The Arava Valley is a rift like structure stretching between the Dead Sea and the

50   Gulf of Aqaba, that is part of the transtensional Sinai-Arabia plate boundary. Several

51   tectonic and structural features control the morphology of the Arava Valley: (1) A series

52   of steep normal faults bound the Arava Valley from both the Jordanian heights in the east

53   and the Israeli Negev in the west (Amit et al., 2002; Garfunkel et al., 2014). These faults

54   contribute to its rift like morphology, with a 5-10 km wide valley bounded by high

55   eastern shoulders and segmented lower western shoulders. (2) A segmented strike-slip

56   system that induces the sinistral offset between the plates (Ginat et al., 1998; Garfunkel et

57   al., 2014; Beyth et al., 2018). (3) Further to the west, extending sub-parallel to the Arava

58   Valley, an asymmetrical wide anticline has been proposed to be reactivated in the Plio-

59   Pleistocene (Wdowinski and Zilberman, 1996, 1997; Ginat et al., 2000) and to induce

60   east or northeast tilt of the central and southeastern Negev toward the Arava Valley

61   (Ginat et al., 2000).

62   In the current research, we focus on the escarpment segment that bounds the

63   Southern Arava Valley from the west. Here, the escarpment is shoulder-type with a major

64   water divide that mostly follows the escarpment cliff. To the east of the water divide,

65   steep basins drain to the southern Arava, and to its west, low relief channels are incised

66   into table-like interfluves and flow west to Biqa't Uvda, before joining the Hiyyon basin

67   that drains to the central Arava Valley.

68   The current drainage configuration differs significantly from the drainage

69   geometry of the previous geologic epochs (Avni et al., 2000). Prior to the formation of

70   the Sinai-Arabia plate boundary, in the early Miocene (Garfunkel et al., 2014), large

71 rivers drained west from Arabia across the present day Arava Valley to the

72 Mediterranean, over an extensive truncated surface that was formed in the Oligocene

73 (Avni et al., 2012; Mart and Vachtman, 2015). In the Pliocene, segments of the central

74 and southern Arava Valley have already formed, acting as local base levels. Nonetheless,

75 other parts were less subdued, allowing a drainage regime whereby areas east to the

76 Arava Valley were drained across the Sinai-Arabia plate boundary toward the central

77 Negev. Finally, during the early quaternary, a major phase of drainage reorganization

78 redirected large drainages of the southeastern Negev to the central Arava Valley by a

79 series of capture events (Avni et al., 2000; Guralnik et al., 2010).

80   The climatic conditions are hyper-arid with precipitation rate $\lesssim$50 mm/yr. It was

81 suggested that with the exception of relatively short-lived episodes of more humid

82 conditions during the late Pliocene and Pleistocene (Beyth et al., 2018; Vaks et al., 2013),

83 the current hyper-arid conditions have persisted since the late Pliocene (Vaks et al.,

84 2013).

85

86

87

88

89

91   Method 1: **Calculating the χ map**

92   Figure 3 in the main text depicts a χ map of the study area and of the basins that drain the

93   escarpment to the east. χ was calculated over the drainage network defined by using a

94   threshold drainage area of 50 pixels (pixel dimensions are 30x30 m). χ was defined using

95   the equation (Willett et al., 2014):

96      $\chi(x) = \int_{x_b}^{x} \left(\frac{A_0}{A(x')} \right)^{\theta} dx'$

97   with $A_0 = 1$ m^2, $\theta = 0.3$, which was found to linearize the main trunk and tributaries

98   (Perron and Royden, 2012) of the largest basin, and x_b is set to be at elevations of 135 m.

99

100   Method 2: **Producing DEMs using drone acquired aerial photos and determining**

101   **terrace extension**

102   We generated high resolution DEMs and orthophotos for channels 10 and 25 in table

103   DR1 from aerial photos acquired by a DJI Phantom III drone with ~80% overlap between

104   the photos. The DEMs and the orthophotos were produced using the Agisoft 'Photoscan'

105   commercial code that applies a SfM algorithm. Differential GPS was used to accurately

106   locate 20 anchoring points in each site. The longitudinal profiles of the active channels

107   and the terraces (Fig. 3E and 3F) were extracted from the DEMs and validated against

108   field mapping.

109   The horizontal extent of the terraces shown in Fig. DR8 was determined by a four steps

110   procedure using ArcGIS: First, a slope raster was generated and a threshold slope (2° in

111   fig. A, 7° in Fig B) was used to define pixels of low slope. Second, regions with high

112   density of low-slope pixels were identified by dividing the region to coarser pixels (1 and

113   1.4m for fig. A and B respectively) and searching for the number of low-slope fine pixels

114   within a 1m radius circle that was centered in each coarse pixel. Coarse pixels with low

115   density of low slope fine pixels (<3.8% and <5.5%, in fig. A and B respectively) were

116   eliminated. Third, the circumferences of areas with high density of coarse pixels that are

117   not part of the channels were defined as terraces and mapped as polygons. Finally, the

118   terrace polygons were validated against field mapping of terraces and final editing was

119   performed.

120   In the upper Shaharut east basin, channel 25 in table DR1 (Fig. DR8A), the areas that

121   were disturbed by a dirt road were eliminated from the terrace polygons. In the same site,

122   the channel might also be disturbed by the dirt road, but the water divide and the

123   waterfall locations and elevations are likely unaffected, so the road does not have a

124   significant effect on the channel profile.

125

126   Method 3: **Defining the northing trend**

127   Figure 4B shows the length of the reversed channels as a function of a northing trend.

128   Northing was defined based on the Euclidian distance to the southmost windgap, No. 38

129   in table DR1. Each channel is represented by its transect point with the cliff, which is

130   either a waterfall or a saddle.

131

132   Method 4: **Measuring the apparent thickness of the erodible valley fill layer**

133   Column 8 in table DR1 reports the apparent thickness of the erodible fill unit into which

134   the reversed channel incises. The apparent thickness was defined as the elevation

135   difference between the windgap (which is consistently located on top of the erodible fill)

136 and the closest contact between the erodible fill and the underlying bedrock (Fig. DR7),

137 which was typically at or slightly upstream from the lip of the waterfall. Bedrock

138 exposure location was identified in the field, and by using field photos and orthophotos.

139 Where we identified valley fill on the waterfall (no. 36 in table DR1), we added its

140 thickness to the estimation of the apparent thickness. The true fill thickness (as opposed

141 to the apparent thickness) is expected to be larger due to the westward grading of the

142 antecedent channels. The estimation of the true thickness requires knowledge of the

143 antecedent slope, which is rarely preserved.

144

145 Method 5: **Automatic calculation of tributary junction angle**

146 Column 9 in table DR1. reports the tributary junction angle for barbed tributaries. The

147 junction angle was calculated automatically using a Matlab script. Upon manual selection

148 of a tributary channel head and the tributary junction points, the script calculates the

149 orientation of two lines. The lines are defined based on orthogonal linear regressions

150 through the pixels of the drainage network. The first line uses the drainage network pixels

151 between the two chosen points. The second line uses the pixels between the junction

152 point and a point that is located upstream from it, at a distance which is half of the along

153 flow length of the tributary. The junction angle is defined as the difference between the

154 orientations of the two lines.

Figure DR1. Barbed drainages in Fall Run, a tributary of the West Fork river, West
Virginia. A. General Location map. B. Zoom-in location map. West to the water divide,
steep, west flowing channels incise the highlands. C. Reversed channels with barbed
tributaries. Here, the headwater of a reversed channel is incised in a mapped alluvial unit
(Cardwell et al., (1968)) that fills the antecedent, east flowing valley.

(5) FIGURE DR2.

168
169 Figure DR2. Barbed drainage morphology in the headwaters of the Clyde river near the
170 great escarpment of eastern Australia. The barbed drainage indicates drainage reversal in
171 the Clyde river. This is a single example out of many along the great escarpment of
172 eastern Australia (Ollier and Pain, 1997; Ollier, 1995; Seidl et al., 1996) A. General
173 Location map. B. Zoom-in location map, depicting the shoulder-type escarpment (i.e.
174 Matmon et al., 2002), and referring to panel C and D. Reversed channels with barbed
175 tributaries in C and hook-shape headwaters in D. Note the embayment of the escarpment
176 along the reversed channels.
177
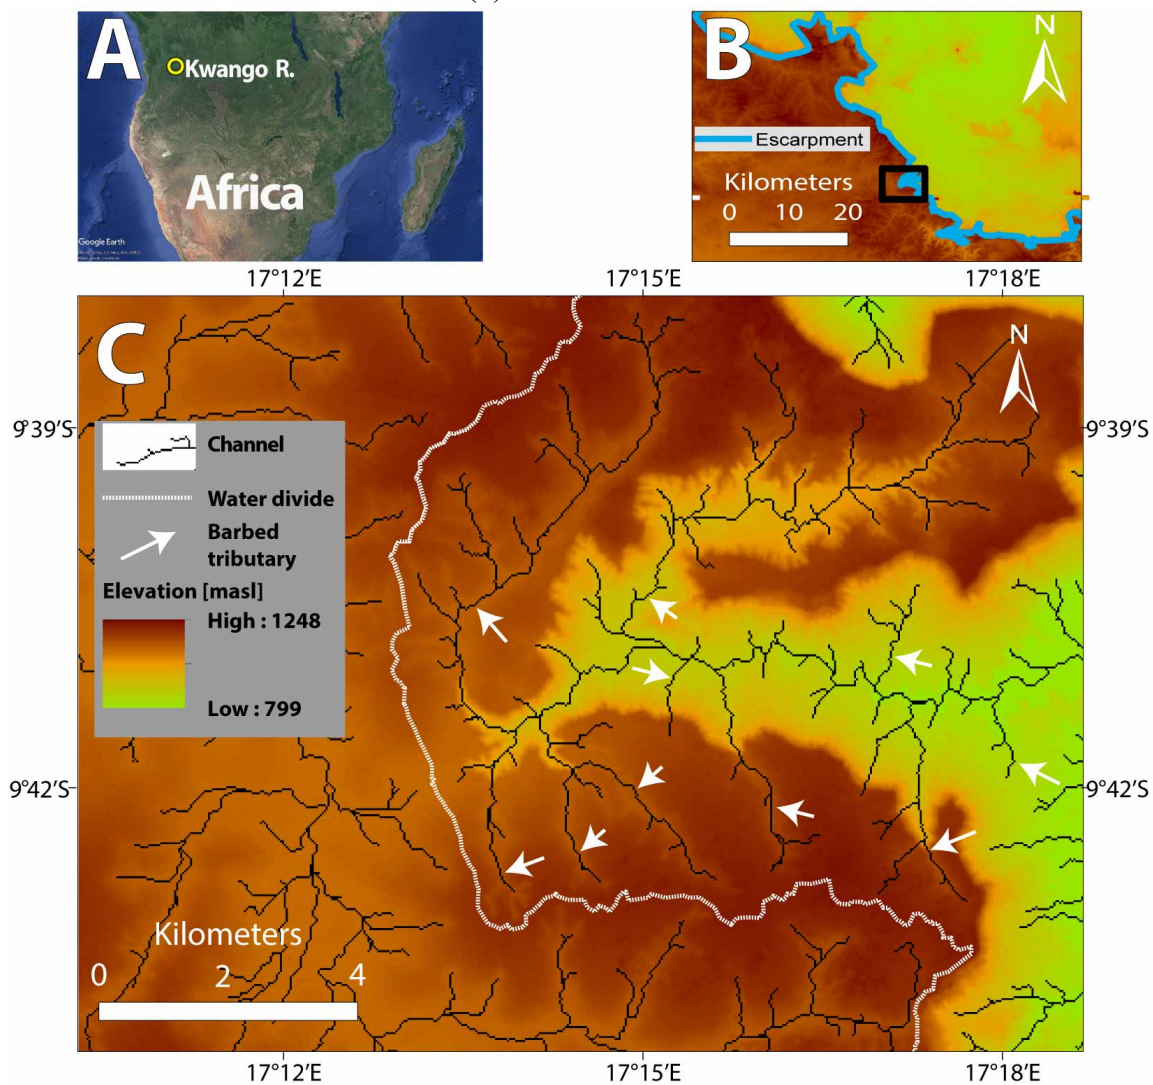

Figure DR3. Barbed drainage morphology in the headwaters of the Kwango river, Angola, near a shoulder-type escarpment. A. General Location map. B. Zoom-in location map, depicting the escarpment. C. A large basin with barbed tributaries that flow from the highland across the escarpment. Note the extreme embayment of the escarpment, which probably occurs through knickpoint migration along the reversed channel.
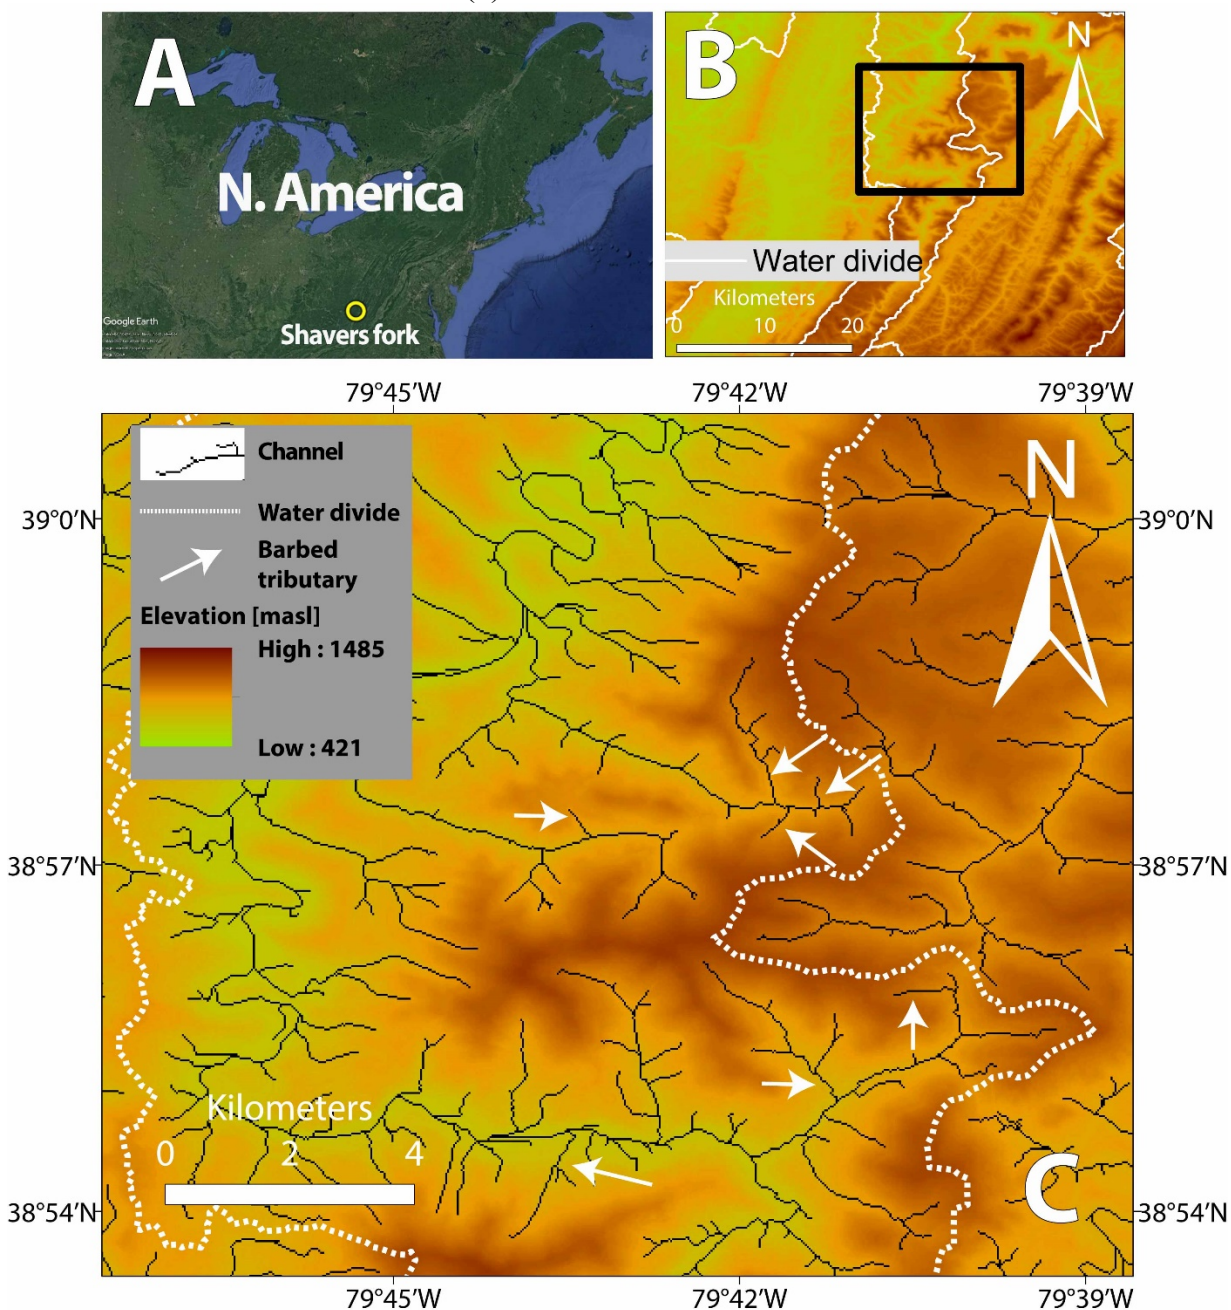

Figure DR4. Barbed drainages in the Shavers fork, near an erosional escarpment in West Virginia. A. General Location map. B. Zoom-in location map. The highland is incised by large channels that drain northward. C. Reversed channels with barbed tributaries drain the highland across the escarpment. Note that in this example, reversal occurs toward an erosional escarpment, which is not part of the Appalachian continental divide.
(8) FIGURE DR5.
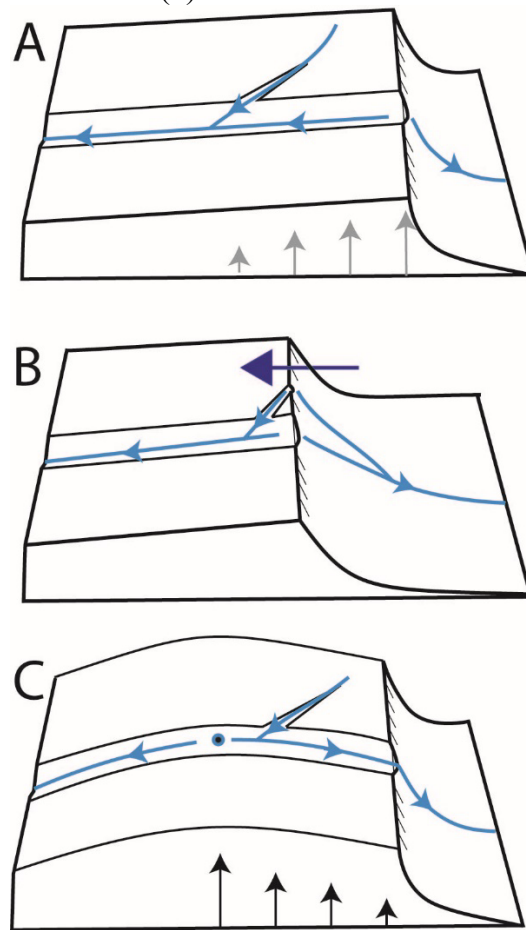

Figure DR5. A cartoon showing the expected effect of tectonic tilting and cliff retreat on diverging channels across a cliff. A. Tilting away from the cliff, depicted by the gray arrows, is predicted by geodynamic models for great escarpments (Gilchrist and Summerfield, 1990; King and Ellis, 1990). Such tilting hinders reversal towards the cliff. B. Simultaneous cliff and divide retreat (blue arrow) erases the antecedent drainage pattern and cannot produce reversed drainages. C. Tectonic tilt toward the cliff (black arrows) could induce flow reversal toward the cliff (Bishop, 1995), but a general source for such a tilt is not recognized.

217

Figure DR6: Field photos showing two stages in the evolution of reversed channels that
flow toward the escarpment. A. View of a wide truncated valley full of sediments (the
white circle marks a person's figure for scale), that formed by escarpment retreat. A short
reversed channel (no. 36 in the supplementary DR1 table) incises in the erodible fill
toward the Arava Valley. B. View of Itro east valley (no. 10 in the supplementary DR1
table), that incises into erodible terraces that cover the channel bed. Note the contrast
between the hard limestone that caps the interfluves and the more erodible colluvial-
alluvial deposits that fill the valley. C. Close-up on a sediment fill outcrop within a
terrace in Itro east valley, showing alternating silts and angular small gravel, mixed with
colluvial large boulders of up to few tens of cm. Hammer for scale.

228

(10) FIGURE DR7.

230

Figure DR7: A conceptual cartoon showing the expected correlation between the thickness of the erodible fill and the length of the reversed channel segments. The source of the fill can be fluvial, from the antecedent channel, or colluvial from the adjacent hillslopes. The dashed lines represent the course of the reversed segments that incise into the erodible fill, and the transparent grey line is the water divide elevation. The profile of the reversed channels can vary from immature convex to mature concave. Here, for simplicity, it is depicted by a straight dashed line, whose slope is similar in magnitude and opposite in direction to the antecedent channel slope, producing transiently stable divide. A and B for thin and thick erodible fills that produce short and long reversed segments, respectively.

242
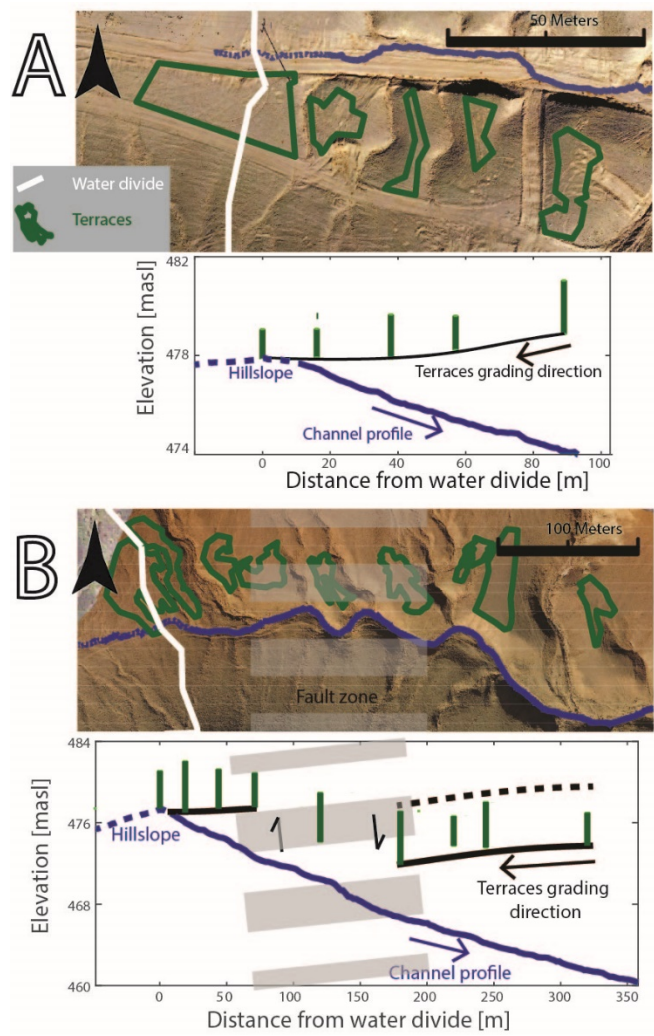

Fig. DR8. Drone acquired aerial photos of reversed channels showing east flowing channels incised into west grading terraces. In each site, the terraces, the channel route and the divide are shown over the aerial photo (top). The longitudinal profile and the projection of the terraces are shown at the bottom. The green bars indicate the maximum and minimum elevation of each terrace and the black curves show an interpreted surface that grades to the west. A. Upper Shaharut East Basin (see methods DR1). B. An upper reach of Itro East Basin. Here, we mapped a steep fault and propose that it offsets the east group of terraces downward by 5-6 meters with respect to the west terraces. The dashed black line shows the reconstructed elevation of the lower extent of the east terraces prior to faulting.
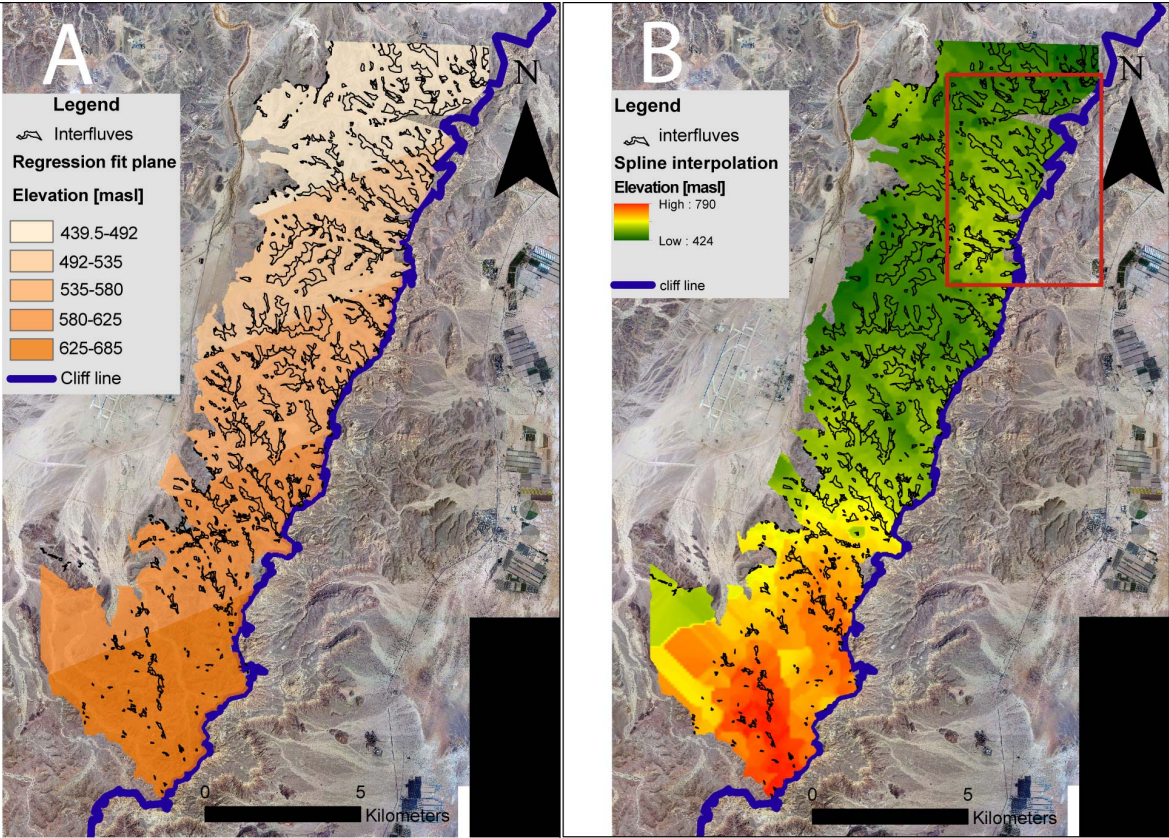

Figure DR9. A. Linear regression plane based on the elevation of the flat interfluves (small black polygons) in the study area. The interfluves were extracted automatically by identifying low relief surfaces far from channels and were validated by visual inspection. The surface shows highland grading to the northwest, which is not expected to contribute to eastward flow reversal. The blue line marks the escarpment edge, separating the southeastern Negev highland at the west from the Arava Valley at the east. B. Spline interpolation surface, based on the elevation of the flat interfluves in the study area. Note that although the spline surface generally grades to the northwest, small regions along the north part close to the cliff edge (in the red rectangle) show local gradient to the north or northeast.
